Dr. **Peter H. Bryce** of Toronto, Ont., stated that the American Public Health Association last year appointed a special committee to investigate the subject of vaccine virus, the speaker being the chairman of that committee. The committee had endeavored to gather facts bearing on the question, and had taken the trouble to visit some of the larger manufactories. This report would be presented with its conclusions at the forthcoming meeting of the American Public Health Association.

He was glad to hear what Dr. Abbott had said in regard to antitoxin. He believed that vaccine virus could be produced quite as well by private concerns as by a government laboratory. He would assume this for the purpose of argument. In England no one handled government vaccine except the public vaccinators, who had received a certificate of efficiency from some educational vaccine establishment, of which there were twenty-five throughout England and Scotland. The public vaccinator was appointed by the government. He received all articles from the national vaccine establishment, or as much vaccine as he proposed to use during one or two weeks. Since the year 1897, when the "conscience clause" was put in the compulsory act in England, the local board had changed its method in this way, that instead of requiring the people, under penalty, to present their children at a public vaccine station within three or four months after birth, it was now the practice for the public vaccinators of England to go from house to house, with a list of the children recently born, and offer free public vaccination to the mothers of these children. This was the present procedure, and it had worked admirably.

In Germany there were twenty-five local government vaccine establishments. In Germany no person, except a trained physician or public vaccinator, could vaccinate anybody If it could be shown that a public vaccinator was careless in his work, or in the lymph he used, he was subject to heavy penalty.

Speaking of Canada, he said there was no compulsory law in the true sense. True, every child was required to be vaccinated within three or four months after birth, but this was not carried out in Canada except in emergency. In Canada there was no law requiring trained vaccinators. There was no means by which lymph could be sent out systematically from any one station, or from any one person who was made responsible.

With reference to the establishment of a national or federal laboratory or institute, where lymphs and serums could be manufactured, so far as he was concerned, he would not encourage any such thing in his own province until he was perfectly sure that the work of vaccination would be put into trained, certified hands, and that it would be done in such a systematic and routine manner that lymph would certainly be used within a week or two while it was still fresh.

Dr. J. F. Kennedy of Des Moines, Ia., suggested that the conference formulate a definition of vaccination.

Dr Gardner T. Swarts of Providence, R. I., said that two or three years ago he read a paper on whether States should control the manufacture of vaccine virus, or whether it should be left to municipal authorities or private manufacturers, and previous to the preparation of the paper he visited nearly all the commercial establishments that produced vaccine virus, and made a partial report to the society. If State boards of health were large enough and could obtain a sufficient appropriation, or the State was large enough to warrant an appropriation to carry on the manufacture and production of vaccine virus and antitoxins, it was all very well. When it came to a small State like Rhode Island or Delaware, the amount of appropriation needed would be so small that it would be impracticable for the State to control an institution of this kind. If these products could be manufactured by the national government, there would be some assurance of purity, but the question arose, as in the case of St. Louis, whether State boards or city boards, which were controlling these products, would not fall into the hands of political schemers, and the result would be that those who produced the virus were not responsible parties, and the State might suffer as a consequence. There should be some control whereby these institutions and their products could be subjected to inspection.

Dr. John Guiteras of Havana, Cuba, said that compulsory vaccination and the preparation of vaccine virus had been carried out successfully in Cuba. There was a board or central station for the elaboration and preparation of vaccine, which was sent all over the island, handled by State officials who were vaccinators. During the last two years compulsory vaccination had been carried out, with the result that smallpox had not been able to gain a foothold in Cuba, although the island was surrounded by countries in which smallpox was quite prevalent.

Dr. John S. Fulton of Baltimore, Md., in discussing the paper of Dr. Probst as to the question, When shall the State Board of Health send at State expense a representative to establish or verify the diagnosis of smallpox?, said that in Maryland, when there was any doubt as to the diagnosis of this disease, it was always subject to verification by and at the expense of the State Board of Health. Coming from a small State, he could not see how in a State as large as Ohio any great expense would come from that practice, and he believed the State should send a representative in all cases of doubt. It was the practice in Maryland to send someone to verify the diagnosis whenever it was desired. It had been his invariable practice to confront the physician as speedily as possible who disputed the diagnosis, and insist that he be called in consultation.

Dr. Probst, in closing the discussion, urged vaccination, even with the virus at present to be had, although an effort should be made to avoid the accidents that occurred here and there. Some assurance should be given the public by saying that this or that vaccine virus had been examined by the State Board of Health, and found to be safe to use.

On motion of Dr. E. W. Cooper of Camden, Del., the whole subject was referred to a committee, consisting of Drs. Wingate, Probst, and Bryce. This committee subsequently presented the following report:

1. That vaccination may be defined as follows: An inoculation, by scarification, puncture, or injection beneath the epidermis, of a vaccine which produces, with some constitutional disturbance, the typical vaccine vesicle, which leaves, after the pock has healed, its characteristic scar

2. That in order to obtain the most satisfactory results, vaccine must be produced either by federal, State, or provincial officials, or by private producers under the closest supervision of qualified government officials.

3. That for the greatest protection against smallpox, State and provincial laws should provide machinery whereby certified public vaccinators can be appointed for the systematic vaccination by house-to-house visitation, of all children born during any year, and at public stations or otherwise of such others as circumstances may make necessary.

4. That the evidence of successful vaccination of all school children naturally forms a part of any system of public vaccination and certificates of such should be accepted only when signed by a municipal or local health officer.

5. That in order that the best results may be obtained, it is essential that medical colleges should be urged to provide for thorough instruction in the theory and practice of vaccination, and that all licensed physicians should hold certificates of having had practical instruction in the operation of vaccination in medical colleges, dispensaries, or public vaccine stations.

On motion, the report was adopted.

Summer Resorts.—Dr. C. A. Lindsley of New Haven, Conn., treated the subject under the following heads:

The Tented Camp; The Million-Dollar Hotel; The Variety of Guests Who Are Entertained at Them; Their Temporary Occupation: The Brevity of the Visits of the Great Majority of Those Who Frequent Them, and Their Sense of Responsibility While Being There; The Enormous Increase of Population When the Summer Influx Is Compared with the Permanent Residents of the Remainder of the Year; The Colonies of Cottages Clustered in Close Proximity and the Risk of Unsafe Results to Health from All These Peculiar Conditions.

Methods of Quarantine against Yellow Fever Adopted in Havana, Cuba, During the Year 1901.—This paper was read by Major W. C. GORGAS, surgeon, United States Army: With the object of excluding the infection of yellow fever, quarantine had been very generally resorted to, and had been enforced by keeping out people sick with yellow fever, and by holding all non-immunes coming from an infected point five days from the time of their last exposure to infection. The period of five days was fixed upon as being, with very few exceptions, the limit of the stage of incubation. As soon as a case was reported, if not sent to the hospital, it was strictly quarantined. Trusted guards in the employ of the sanitary department, in eight-hour shifts, were placed over the rooms quarantined, and nobody was allowed to pass except the physician in attendance. After the case came into the charge of the sanitary department, nobody was allowed to leave the quarantined area for any cause whatever, and no one except the physician was allowed to enter it. On the termination of the case, all fabrics of every kind which might contain infection were taken to a central station at Las Animas Hospital, and were sterilized in a large sterilizer with steam or formalin, as was thought best. The quarantined area was then carefully scrubbed with a bichloride solution, 1-1000, and sprayed everywhere, by means of a force pump, with the same solution, and then the rooms were closed and sealed, and disinfection with formalin at the rate of 1 liter to 1,000 cubic feet of air space was made, and the rest of the house was well scrubbed and cleaned with soap and water, and afterward sprayed with a bichloride solution of the same strength.

Early in 1901 the Army Board put forward the theory which they had demonstrated, and which Dr. Finlay had, for the past twenty years, maintained, that the mosquito was the means by which yellow fever was conveyed from patient to patient, and the only means, and that it was not conveyed by fomites and articles soiled by the yellow-fever patient.

As the result of the acceptance of this theory by the sanitary department, changes were made in the quarantine regulations. If the disease could be transmitted from a sick person only by the mosquito, there would be no occasion to give any care to the bedding, fabrics, etc., soiled by the sick person, or that came from the infected locality. In accordance with this view, the quarantine regulations of the city were modified. When a case was reported as yellow fever, the quarantined area was at once screened at public expense, with the idea of keeping infected mosquitos in, and of keeping out all mosquitos that had not been infected. A guard was placed over the quarantined area to see that the screen door was kept closed. A limited number of immunes, six or eight, were allowed to be designated by the physicians in charge, who could have access to the quarantined area. When the case terminated, all the mosquitos were killed by fumigation with pyrethrum powder, but no attention was given to clothing, fabrics, etc. In Havana pyrethrum powder was used in fumigating for yellow fever, for the reason that it was not objectionable to the people whose premises were being fumigated. It is a poor culicicide and does not kill the mosquito with any certainty. In every fumigation a considerable number will be found merely intoxicated, and will revive if given access to fresh air. Sulphur, tobacco, and other substances are very much more deadly to the mosquito, but it was feared that if the people were caused too much inconvenience it would result in cases being concealed, and this would defeat the success of the work. Believing that the infection was carried only by the mosquito, and that microorganisms which had escaped from the body of the sick person in any way and were preserved in the clothing and fabrics around the room could do no harm, these things were left alone. At the termination of the case the mosquitos in the house and in adjoining houses were killed, the screens [illegible] down, and the guards withdrawn. This was the [illegible] of quarantine put into effect with regard to cases [illegible] in the city.

From the time the system was adopted up to the end of the year, 1,250 non-immunes were reported as coming from infected localities. Of this number, twenty [illegible] were discovered to have yellow fever, or developed it within the period of incubation.

The author believed that under the system of inspection as enforced in Havana during 1901 yellow fever would no more frequently get into the United States than it had during the past years of rigid quarantine. The relief to commerce under such a system would be enormous. With present knowledge and experience, he advocated as a quarantine against yellow fever, both land and maritime, that infected vessels, or vessels coming from an infected port be carefully fumigated, so as to kill all mosquitos in water every part of the vessel. This would apply to ships and all cars and other vehicles on land. That the passage of merchandise, baggage, etc., be interfered with in no way whatever. That passengers, when sick, be quarantined and isolated; that all other passengers be allowed to pass freely; that non-immunes from infected points be seen once a day by a medical inspector, and if at the end of five or six days they were well, they be released from all surveillance.

Method of Stamping Out Yellow Fever Suggested Since 1899.—Dr. CHAS. J. FINLAY of Havana, Cuba, contributed a paper on this subject. His conclusions were:

1. That the germ of yellow fever is only pathogenic for human beings when introduced by inoculation.

2. That the regular process by which the inoculation of a germ is accomplished in nature is through the bites of the stegomyia fasciata, the insect having previously become contaminated through the act of biting yellow-fever patients within the first five or six days of their attack.

3. That although the bites of a recently-contaminated mosquito can produce only a mild attack of yellow fever or simply confer latent immunity without eliciting any pathogenic reaction, the bites of the same insect, when its contamination dates back from several days or weeks may be expected to produce severe or fatal attacks of yellow fever.

4. That the yellow-fever mosquitos, after they have once been contaminated, retain the power of inoculating the disease during the rest of their lives if they have the chance of biting non-immunes.

5. That the essential conditions for stamping out yellow fever from an infected locality are (*a*) to protect yellow-fever patients from the bites of the special yellow-fever mosquitos; (*b*) to destroy all mosquitos which may have reached yellow-fever patients; (*c*) not to allow non-immunes to enter the infected zone until the last of the contaminated insects may be supposed to have died; (*d*) to lessen the chances of propagation by adopting adequate measures calculated to prevent the multiplication of mosquitos in general.

6. In 1898, when the author reckoned the longevity of the stegomyia at thirty-five to forty days, as a maximum he fancied that his theory would be improved by including also the possibility that the infected insects might transmit their infection to their progeny, as the cattle-tick is supposed to do with regard to Texas fever. The reasons which induced him to make that suggestion ceased to exist from the moment that the United States Commission proved that some of the stegomyias live as many as seventy or more days, and the author was not sorry to give up an idea which did not fit readily his theory.

Major W. C. GORGAS presented the following resolution:

Resolved, That in view of the establishment [illegible] that yellow fever is transmitted only by the mos[illegible] conference is of the opinion that there is no lon[illegible] sity for the disinfection of clothing in yellow-fe[illegible] bedding, fabrics, or effects of any kind, but simply to take measures looking to the control of the sick and the extermination of infected mosquitos. In cases in which non-immunes have been exposed to infection, they should be observed during the period of incubation.

The above resolution was the report of the committee on yellow-fever resolutions, and was signed by Drs. Gorgas, Ross, and Glennan.

Dr. J. S. Stephens of Natchitoches, La., representing Dr. Arthur Nolte of the Louisiana State Board of Health, submitted a minority report, to the effect that the mosquito was not the only mode of transmission of yellow fever, he and his confrères believing that fomites carry the disease. Experience in the past had been extensive in that regard. Believing, therefore, that both the mosquito and fomites were modes of transmission of the disease in Louisiana, the same quarantine was maintained to-day that was carried out years ago, with slight modification.

After a spirited discussion, participated in by several members of the conference, Dr. John S. Fulton of Baltimore moved that both the majority and minority reports be spread upon the proceedings, but that the conference do not commit itself to any expression concerning the practical measures to be used in restricting yellow fever. This motion was adopted.

An address of welcome was delivered by Prof. Wm. H. Brewer, President of the State Board of Health of Connecticut, after which came the delivery of the presidential address.

The State in Its Relation to the Tuberculous was the title of the presidental address delivered by Dr. H M. Bracken of Minneapolis, Minn. He considered the subject under the following heads: (1) The care of the advanced or incurable cases; (2) The care of the incipient cases; (3) The protection of the uninfected.

In studying these three groups, the author reversed the order, considering first the advanced or probably incurable individuals. Humanity demanded that we should care for these. The last United States census gives the total number of deaths during the census year from this one disease as about one hundred and ten thousand. Undoubtedly, a large proportion of these patients were too poor to care for themselves during the latter part of their illness. It can thus be seen that there is a great demand upon the municipality or State to care properly for these unfortunates. Looked at from an economical standpoint, he thinks it is wise to provide special hospitals for such cases rather than to thrust them upon the general hospitals, where they may infect the non-tuberculous patients. Humanity demands that the tuberculous poor should be decently housed. Discretion, as well as humanity, demands that the incurable tuberculous shall be properly cared for.

The present method in vogue in certain State institutions of drawing a line between the advanced and the incipient cases of tuberculosis, and saying to the former, "Go hence; we cannot cure you; we do not want you; you cannot get well; go home and die, while we care for those only who may recover," is highly deplorable. It is depressing; it is inhuman. Undoubtedly, a percentage of the advanced tuberculous cases may recover. Why should this class of patients be told, indirectly at least, that they are incurable? Why should not hope be held out to them as long as there is any hope whatever?

The incipient tuberculous demand attention. It is easier to persuade legislators to give money to institutions that can show great results. Every hospital is ambitious to keep its death rate as low as possible. Appeals for institutions for the incipient tuberculous are influenced by the fact that better results can be shown for this class than for the advanced cases, and the feeling prevails that it is through results we must appeal to legislators.

He inclined to think that the municipal sanatoria should have an advantage over any single State sanatorium. He did not wish to be understood as opposing the latter, but rather as asking for more than it can offer. The people will take an interest in a local institution when they would give little or no attention to a State institution.

If it is a public responsibility to provide for all tuberculous individuals, it is an imperative duty to protect the non-tuberculous. This can only be done by removing all tuberculous individuals from the homes or places of residence where they are a source of danger.

In closing this address, Dr. Bracken suggested that the conference would accomplish the greatest good by the formulation of some rules that might serve as a guide in securing favorable legislation. He therefore made the following propositions for consideration:

That physicians, or those having the care of tuberculous individuals, be required to report the disease to local health officers.

That local boards of health should be required to register all tuberculous individuals within their jurisdiction.

That the proper care of the tuberculous be urged upon State and municipal authorities, and that the construction of sanatoria and isolation hospitals be insisted upon.

That the advanced cases of tuberculosis be recogized as demanding attention equally with the incipient cases; (1) in order that they may have every possible chance to recover; (2) in order that the danger of infection through them to others may be removed; (3) in order that the incurables may be well cared for so long as life lasts.

That it is the duty of the State and the municipalities, singly or jointly, to provide for the proper sanitary care of all tuberculous individuals, either at their homes or in hospitals and sanatoria.

That the various States and provinces here represented place themselves on record as urging the necessity for the establishment and proper maintenance of State and municipal institutions for the care of the tuberculous.

A committee was appointed to make rules governing the transportation of the dead.

The Plague in San Francisco.—Professor F. C. Robinson of Brunswick, Me., presented the following resolutions, in behalf of the State Board of Health of Maine, expressing the opinion of the conference as to the conduct of the health authorities of San Francisco in dealing with the plague question:

Whereas, Thirty cases of plague have occurred since July 13, 1902, no information as to their origin or exact location having been furnished, no effective steps having been taken to restrict the spread of the disease, the City Board of Health of San Francisco being helpless, and the *mala fides* of the State Board of Health of California having been fully established by the history, supported by documentary evidence in the possession of this conference; therefore, be it

Resolved, That the conference of State and Provincial Boards of Health of North America views with abhorrence the irretrievable disgrace of the present State Board of Health of California, and pronounces the plague situation in California a matter of grave national concern; and be it further

Resolved, That the national conference of State and Provincal Boards of Health of North America does hereby advise the various State boards of health of the United States to consider the propriety of calling upon the Surgeon-General of the United States Public Health and Marine Hospital service to arrange at the earliest possible date a joint conference for the purpose of eradicating the plague from the United States.

The resolutions were unanimously adopted.

Dr. Cressy L. Wilbur of Lansing, Mich., read two papers, one entitled "Progress of the Movement for

Uniform Statistics of Causes of Death," and the other, "How Shall Births Be Registered?"

Some Recent Evidence as to the Spread of Typhoid Fever.—Dr. Henry B. Baker of Lansing, Mich., followed with a paper on this subject. In about 25 or 30 per cent. of the cases of typhoid fever, the urine contains vast numbers of the specific microorganisms which cause the disease; also that this condition sometimes remains for a considerable time after apparent recovery, and that cystitis, months after recovery from the fever, may be due to the continued presence of typhoid bacilli in the bladder. This is one reason why typhoid fever is sometimes spread more or less directly from person to person, and is so likely to occur in a camp to which it might be supposed only well persons go. It emphasizes the importance of proper disposal of the urine, as well as the bowel discharges at all times. Human urine and other excreta should be considered by sanitarians as generally liable to contain the specific cause of typhoid fever.

The habits of flies, when considered in connection with present knowledge of the presence of the bacilli of typhoid in the urine and other excreta, make plain the danger of all camps to outbreaks of typhoid fever, and should make it possible to prevent and restrict such outbreaks.

The essayist quoted Dr. V. Stuhlern, who was the first in recent times to prove the existence of typhoid bacilli in the sputum.

In closing, the author said that typhoid fever is restricted by isolation of cases and disinfection of all infected articles.

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. Irving A. Watson, Concord, N. H.; *Vice-President*, Dr. John Guiteras, Havana, Cuba; *Secretary*, Dr. Gardner T. Swarts, Providence, R. I.; *Treasurer*, Dr. James A. Egan, Springfield, Ill.

The time and place for holding the next annual conference were left to the executive committee.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 16, 1902.

Charles L. Dana, M.D., Vice-President, in the Chair.

Pathology and Treatment of Epilepsy.—Dr. William H. Thomson presented a paper on this subject. He said that the more the pathology of epilepsy was understood, the more it became known that epilepsy stood alone among nervous diseases. At the outset of such a study one was confronted with some difficulty in defining what was meant by epilepsy. It could not be defined as a convulsive disease, or as one characterized by loss of consciousness, for these features were not constant and invariable phenomena of epilepsy. Epilepsy was a specific disease, and no other was so protean in its manifestations. A non-convulsive case might, at any time, change into a convulsive one, or *vice versa*. The mistake was often made of looking upon some one apparently unimportant symptom as a prodrome of the disease rather than as a part of the disease. The one unvarying element which constituted the pathognomonic feature of epilepsy was suddenness. Many diseases were rapid in their onset, but not instantaneous as was epilepsy. The phenomena of this disease were dependent upon a disturbance of the normal relations of nervous force and inhibition. The beginning of every nervous action was always on the afferent side, and in epilepsy there was no exception to this rule. Inhibition implied an accumulation of nerve force in order to inhibit. The familiar act of sneezing began with an aura in the nose, and then spread widely through the respiratory muscles. There were many striking examples of the fact that any new afferent excitation might become quite dangerous in its effect. Some toxins circulating in the blood seemed to give rise to convulsions, and affected primarily the peripheral nerves. An animal, for example, poisoned with strychnine had a normal appearance until touched; then convulsions were at once excited. From these considerations of the physiology of the nervous system and the pathology of epilepsy, the author defined epilepsy as a "disease characterized by a sudden derangement of the normal regulative inhibition existing between cortical nerve centers, induced, in the first instance, by an abnormal afferent excitation." By this view of the disease its origin was shifted from the motor or efferent to the sensory or afferent side. This afferent theory of the nature of epilepsy was not in the least controverted by the development of the disease from a traumatism to the brain.

Treatment.—The treatment should be begun by a careful examination of the whole patient, and a thorough search for some abnormal afferent irritation. A venous thrombosis in the meninges following such disease as typhoid and scarlet fever, was not an uncommon cause of epilepsy. The greatest area of reflex excitability in the whole body was in the region of the epiglottis, and rapid eating and drinking; therefore, keep this part of the nervous system in a state of abnormal activity The speaker said he felt sure that he had seen certain cases of epilepsy apparently attributable to the habit of eating rapidly and bolting the food. He had seen two cases of epilepsy in which the convulsive seizures had been diminished in severity by two applications of nitrate of silver to the larynx, and he would suggest that an application of nitrate of silver solution, ten grains to the ounce, be made once a week. For many years he had made use of the red pepper pack to the whole body of the epileptic on the theory that by such repulsive measures the abnormal afferent impression might often be turned aside This pack should be made by wringing out a sheet in an infusion of red pepper of the strength of half an ounce to one pint of water. The bromides were often very carelessly administered to epileptics, whereas, the very fact that they must be continued for a long time, made it necessary that unsual care should be exercised to avoid bromism This could be done by promoting the general health by proper hygiene, and by the administration of the bromides in conjunction with phosphorus and cod liver oil. The bromides would also act well when combined with the coal-tar remedies, as, for example, one grain of antipyrin with every two grains of bromide. Chloral was useful as an adjuvant, but should not be prescribed in larger doses than ten grains. In the treatment of epilepsy one should never lose sight of the fact that the system of the epileptic is profoundly perverted, and that nothing which would be likely to improve the general health should be thought too trivial to receive attention. These patients were specially prone to toxæmia, particularly from the intestinal tract. He always prescribed intestinal antiseptics sooner or later, and made it a point to insist that the patient eat very sparingly of meat. Those cases of epilepsy characterized by several seizures occurring close together and then a long interval of immunity, were very apt to be dependent upon intestinal toxæmia. Another fertile source of toxæmia was renal insufficiency, a condition which might be present without albumin or casts being found in the urine. In conclusion, the speaker said that he knew of no one factor which diminished nervous excitability so much as open-air life Possibly this was because under such conditions the tendency to toxæmia was greatly reduced. He would recommend open-air treatment as earnestly for the epileptic as for persons afflicted with pulmonary tuberculosis.

Dr. B. Sachs said he had been deeply interested in the paper, yet he felt compelled to dissent from the conclusions of the author. The opinion that afferent symptoms were responsible for the epileptic attack had been held by many, yet the weak point of this theory seemed to be that all persons were alike exposed to these same afferent stimuli, and yet all persons did not become epileptics. The afferent stimuli were responsible merely for the attacks. Proof was not lacking also that epilepsy was not merely a disease of the afferent system, and that there are substantial changes in the brain, particularly in the cortex which must be held responsible for the greater responsiveness of these persons to afferent stimuli. Epilepsy, therefore, was a disease, the chief symptoms of which were excited by afferent impulses; beyond this, argument did not seem to carry one. Suddenness was certainly a very characteristic symptom of this disease, yet any argument which would tend to lessen the prominence of loss of consciousness as a symptom seemed to him unfortunate and confusing. For a long time he had been accustomed to say that the treatment of epilepsy consisted largely in removing all peripheral causes of epileptic attacks. He believed, in addition to our efforts to remove the abnormal afferent stimuli, we should endeavor to remove the increased irritability of the cortical centers. He was in entire agreement with the reader of the paper as to the great frequency of autoinfection as a causal factor in epilepsy, and the need for treatment directed to the gastrointestinal canal. He had had cases in which extreme care in the regulation of the diet and bowels had accomplished far more than the administration of the bromides and similar remedies.

Dr. S. J. **Meltzer** said that although he had given the subject a good deal of thought, he did not feel like accepting the author's view that epilepsy is essentially dependent upon a disturbance of inhibition. Nor did he think it was necessary to look for an invariable and characteristic feature; certain elements might well be absent at times without vitiating the diagnosis of epilepsy. A distinction should be made between reflex epilepsies and those which we call idiopathic.

Dr. **Pearce Bailey** agreed that neither convulsions nor loss of consicousness were fundamental in epilepsy, yet he did not feel like giving such a prominent place to the element of suddenness. This element was just as [illegible] in myotonia congenita and in some cases of hysteria. Moreover, he did not think the attack was really as sudden as Dr. Thomson seemed to think. Some epileptics had knowledge of an impending attack for about a day beforehand, and this seemed to him to be in the nature of an aura. Some uncertainty regarding the subject under discussion arose from the author's method of considering the epileptic attack and the aura as indivisible. As to the treatment, he would say that his experience with methods directed to allaying peripheral irritation had not been very satisfatory. This treatment had been carried out with great exactitude at the Craig Colony for Epileptics with almost negative result. At the Colony drugs were found the least important part of the treatment; occupation, muscular work, and outdoor life were the chief elements in the treatment.

Dr. **William P. Spratling** of the Craig Colony said it was a rather rash thing for any one to attempt to define epilepsy. Personally, if he were asked to do so, he would decline, and would then reply as follows: "It is a nervous affection, generally characterized by some impairment or loss of consciousness coincident with some impairment or loss of the power of motor coordination, with or without convulsions, the paroxysms being generally abrupt in appearance and short and variable in duration." He would totally disagree with the reader of the paper as to the suddenness of the phenomena of epilepsy, for he saw at the Craig Colony many cases in which the approach of the attack was known for some time previously. The afferent impulse theory did not seem to him necessary; he would rather believe that epilepsy was due to some change in the brain cells, and that an afferent impulse was only needed to bring this out. He did not think that much could be said as yet concerning the pathology of epilepsy, for the lesions found at autopsy in the brain were, apparently, the results and not the cause of the disease.

Prognosis in Epilepsy Often Favorable.—He was disposed to be optimistic regarding epilepsy, for an experience of ten years in the Craig Colony had given him an opportunity of seeing some remarkable results from treatment. As to the latter, the greatest stress was laid upon attention to the diet and to the gastrointestinal tract, and to the benefit of occupation. When a prognosis was given it should be based upon the mental condition. He did not hesitate to say that epilepsy is a curable disease. They had at the Colony records of twenty patients who had left after a stay of two and a half to three years, and who had been away for four or five years, remaining absolutely well. It should be remembered in this connection that there were many varieties of epilepsy, and that those who early show mental impairment afford grounds for a gloomy prognosis.

Dr. W. M. **Leszynsky** pointed out the unfortunate tendency at the present time among general practitioners to at once prescribe the bromides just as soon as the diagnosis of epilepsy had been made. Personally, he was disposed to avoid using the bromides as much as possible, and to place the utmost reliance upon open-air life and suitable occupation, together with measures directed toward securing a healthy state of the gastrointestinal tract.

Dr. **Ralph L. Parsons** of Ossining reported several cases of epilepsy which had been successfully treated and permanently cured by the persistent and systematic use of strychnine, given in increasing doses up to the physiological effect. Massage, general hygienic measures, and colonic washings were also employed.

Dr. **Thomson** closed the discussion. He said that he had not intended to speak of afferent stimuli as causing epilepsy as such, but had endeavored to point out the fact that these stimuli are *abnormal*. For example, by the use of strychnine one could make the peripheral irritability so great that a breath of air would bring on convulsions. Not one of the speakers in the discussion had accepted his challenge to cite a case in which there was a spontaneous afferent motor activity of the nature of an explosion. The differences of opinion brought out in this discussion were more apparent than real.

Anniversary Meeting, November 6, 1902.

Robert F. Weir, M.D., President.

The Past, Present, and Future of the New York Academy of Medicine.—Dr. **Andrew H. Smith** delivered this, the anniversary discourse. He said that the inception of the Academy of Medicine took place at a social gathering in 1846, and in the following year it was formally organized and entered upon its career. The first president was Dr. John Stearns. Valentine Mott, Willard Parker, John Watson, William H. Vanburen, and Alonzo Clark were among the eminent men who had adorned this academy. The former home of the academy was a large dwelling house, but the rapidly-increasing library made it necessary to look for more commodious quarters, and the result was the present edifice. The list of Fellows now comprises 800 names. The publications of the academy were now regularly received by almost every medical library in the world, hence, it was no exaggeration to say that whoever spoke from its rostrum was heard around the world. The annual editions to the library for the past three years had been not less than 3,500 annually, and 991 journals were kept on file, thus adding 1,145 bound volumes each year. During the present year 11,520 readers had registered at the library. The speaker said that the Board of Health was emphatically the child of the Academy of Medicine, the original health department having been formed by the Academy of Medicine, aided by a committee of citizens. He thought it would be well if at the present time a closer relation existed between the Board of Health and the academy, even, perhaps, to the extent of making the board an executive department of the academy. This was only one of many actions taken by the academy for the conservation of the public health. Such activity was as much a legitimate part of the work of the academy as was scientific discussion or the maintenance of a public library. The need for the academy's being in close touch with the health department was illustrated by the wholly unnecessary and disgraceful detention a few years ago of cabin passengers of incoming steamers because of the outbreak of cholera among the steerage passengers. A more intimate relation between the public and the academy would have prevented the wretched maladministration of Bellevue and the other city hospitals. Scientific medicine had certainly failed to obtain the hold which it deserved upon the popular mind, and the medical profession itself was largely responsible for this. We had been content to dig and delve and wrest from Nature many important secrets, and then kept this important knowledge to ourselves. Who was better equipped to educate the public in these matters than those who had discovered these facts or had specially studied them? Only in medicine was it considered undesirable and undignified to give out any information to the laity on subjects of interest to them. This was in sharp contrast with the methods of the Christian Scientists. Their principles, such as they are, were freely and publicly discussed; the only trouble was that there was so little to be discussed. To many persons even these meager discussions were more satisfactory than the shadowy glimpses given to them of the mysteries of true scientific medicine. Anything of an educational nature given out to the public by the Academy of Medicine, or under its censorship, should be looked upon as a guarantee of the genuineness and reliability of the information so furnished. Doing a thing properly was the best way of preventing somebody from doing it improperly.

The Disappearance of Yellow Fever from Havana, Cuba.—Major W. C. Gorgas, U. S. A., formerly Chief Surgeon of Havana, presented a communication on this subject. He said that perhaps many medical men had forgotten that at one time New York City was more subject to yellow fever than Havana, and that Philadelphia was in still worse condition in this respect. The peculiarity of the habitat of yellow fever had always occasioned remark. It had been principally confined to the coast of the Gulf of Mexico, though frequently spreading to other ports. It had never been transmitted to the dense populations of India and China. This limited spread of the disease had long attracted attention, and had been very difficult to explain. However, this difficulty cleared up when the theory was advanced that the mosquito was the intermediary host, for the disease could not be carried in this way to such distant places as India and China. The disease was sharply limited by latitude, north and south, it disappeared quickly on the appearance of frost, and was not usually found in high altitudes. Yellow fever was frequently epidemic at Vera Cruz, and that city was connected with the city of Mexico by a railroad, and had intimate commercial relations with that place; nevertheless yellow fever was not contracted in the City of Mexico. This was probably because the infected mosquito could not live at that altitude. The female mosquito alone bites, and in doing so infects the person, unless the latter was already immune, or unless more than three days had elapsed since the development of the disease. In localities having frost the disease could only be epidemic, even under the most favorable conditions for its development. A considerable number of non-immunes must be added to the population yearly to make yellow fever endemic. So far as could be ascertained from the records, yellow fever had been endemic in Havana since 1762. The large number of non-immunes introduced annually into Havana explained the continuance of yellow fever in that city. From 1836, according to official statistics, up to the time of the the American occupation of Havana there had been frequently as many as one thousand deaths a year from this disease and seldom less than 500 deaths. A sanitary department was at once organized in Havana by the Americans, and the work of sanitation was pushed most vigorously. In the first year of the occupation there were 8,000 deaths, giving a death rate of 33, and in 1900 there were 6,000 deaths, or a death rate of twenty-four. Pretty nearly half of the Governor-General's staff died in 1900 from yellow fever, and there were more cases and more deaths from this disease in the cleanest and most hygienic quarters of the city. About this time Major Walter Reed published his paper, showing that a special variety of mosquito was the intermediary host of the infective agent of yellow fever, and on this basis the sanitary department set out to combat the disease. Usually within two hours after notification of a case of yellow fever the infected house was thoroughly screened so as to prevent the access of the mosquito, and fumigation was practised so as to destroy the mosquitos already on the premises. It was required by law that all water barrels and cesspools be screened, and the larvæ were destroyed by the application of petroleum. Petroleum was never used, however, when it was possible to remove the fresh water collections by drainage. It was now over a year since the last case of yellow fever occurred in Havana. An inspection of that city in January, 1901, just before waging war on the mosquitos showed 26,000 breeding places for the larvæ in the city, whereas a year later the inspection showed only 300 such places. It was surprising how little ditching would make a muddy field comparatively dry. This work showed the feasibility of exterminating yellow fever from the whole world. If yellow fever could be kept out of Havana for twenty years, he thought the disease would be completely exterminated in North America, for Havana had been the great center of infection, and if it could be kept clean the other places would probably gradually clean themselves.

Yellow Fever Not Carried by Fomites.—Surgeon Ross, U. S. N., said that ships now came frequently into Havana with yellow fever, and the sufferers from this disease were taken off the ships and carried through the streets of Havana, a distance of three miles to the hospital. While in transit these patients were kept carefully screened from mosquitos. The precautions instituted by Major Reed had been continued since his departure, so that it seemed that Havana was safe for the future. The speaker then cited instances to show how perfectly the mosquito theory explained all the many hitherto puzzling and contradictory facts known regarding yellow fever. He said he had made experiments which seemed to absolutely exclude the possibility of transmitting the disease by fomites. For example, men had been caused to live in small and ill-ventilated rooms, such as were used by the common people of Cuba, and in contact with fomites for a much longer time than the incubation period of the disease, and yet they had not developed it. He mentioned this because a few persons who had made a study of yellow fever admitted that the disease was propagated by certain mosquitos, but insisted that it might be transmitted in other ways.

Dr. W. B. James said that the present occasion was not so much one for discussion as for commendation of the scientific insight which had pointed the way and the magnificent scientific labors which had culminated in this brilliant and unexpected victory over this dreadful scourge of humanity. These wonderful achievements should lead us to gird ourselves up for a more effective attack upon some of the infective diseases, such as tuberculosis, which continue their ravages within our borders.

Major Gorgas said that it could not be denied that circumstances were specially favorable for this remarkable piece of scientific work—the military government, a medical man for governor, and the presence of several scientists who were engaged in a special study of yellow fever, constituted no ordinary combination.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held October 13, 1902.

Robert T. Morris, M.D., Chairman pro tem.

Plastic Operation Following Removal of Malignant Growth of Cheek.—Dr. Charles H. Peck presented a man, forty-nine years of age, who had been an excessive smoker with both pipe and cigar. For a number of years there had been a sore in the angle of the mouth, but he had paid but very little attention to it until about four months before coming under observation. At that time the inner surface of the cheek was occupied by an ulcer which involved nearly all of the mucous membrane, only a small portion of the angle of the mouth, however, being implicated. There was enough normal tissue left at the reflexion of the gums to allow of proper excision. The growth was excised and the gap closed by a sliding flap, the base of which was over the masseter muscle. The mucous membrane being entirely destroyed, none could be obtained for lining the flap, so this surface was left to granulate. Another flap was also slid from under the chin. The healing process went on rapidly and satisfactorily, and, while there was considerable cicatricial contraction and some ankylosis, the patient could not open his mouth quite well. The operation was done on August 18, and he was discharged on September 2.

Dr. John F. Erdmann said that he had done a very similar flap operation to that done by Dr. Peck, and in that case the disease had not recurred for eleven months.

Dr. Martin W. Ware said that Dr. Peck was to be congratulated on the good cosmetic obtained. The ankylosis had probably resulted from the absence of mucous membrane. When in Europe, he had seen Israel fill in such a gap by a pedicle flap, the skin side of which was turned in so as to form mucous membrane.

Dr. Peck said that he had considered this method, but had decided it would be impossible to do this on account of the beard, and he did not wish to disfigure the man by taking a flap high up under the eye.

A Case of Spina Bifida.—Dr. Frederic Griffith related the history of a case of spina bifida (this report will appear later).

Dr. R. T. Morris said that the cases he had treated by operation had shown a strong disposition to leak even after the smallest punctures with the finest silk. This leakage could be largely avoided by using powders which repel water. Immediately after the suturing, aristol, or the stearates in powder, should be pressed upon the punctures.

Pre-operative Preparation of the Surgeon and His Assistants.—Dr. George R. Fowler was the author of this paper He said it was generally admitted that the street clothing of the surgeon and his assistants should be completely covered if it were impracticable to remove it, though the latter was preferable.

Hand Disinfection.—The recent literature upon the so-called disinfection of the hands alone was most voluminous, yet the bacteriological examinations showed that it was practically impossible to render and maintain the hands sterile. It had long been known that the subungual spaces were a fertile source of infection. The general cleansing of the hands by combined mechanical and chemical means was, perhaps, the best. Often fissures were formed around the nails, and where the skin was sensitive, and, indeed, probably in all cases, folds of sterile gauze could be substituted for the nail-brush. He had long looked with suspicion upon the ordinary metallic nail-cleaners because of the traumatisms they produced. At one time he had endeavored to avoid this source of infection by trimming the nails so closely that there was practically no ungual space. This plan answered fairly well as regards infection, but the consequent loss of tactile sense, and the inability to pick up small instruments because of not having projecting nails, had made him finally abandon this method. He had recently found that an admirable method of cleansing the nails was by seesawing with the selvage edge of common gauze. A more convenient way of carrying out this idea was by using a steel-spring wire frame, like that for the keyhole saw, and substituting for the saw a small round brush. Such a device Dr. Fowler exhibited. Immediately after alcoholic disinfection of the hands, they were usually sterile, but after placing the hands in warm water for some minutes and irrigating with sterile sand, it would be found that the microbes would soon come to the surface.

Rubber Gloves.—He believed rubber gloves were useful, but their field of usefulness was limited to certain examinations in very septic cases, and they could not be employed where delicate tactile sense was required. There was scarcely an operation in surgery that did not risk the tearing or puncturing of the gloves; moreover, the interference with the tactile sense and the catching of the needle in the glove made them very inconvenient. Worst of all, the poulticing of the hands arising from the use of rubber gloves caused the passage of myriads of micro-organisms to the surface of the hands, and hence when the gloves were torn or punctured, infection was actually favored by the use of the gloves. Dr. Fowler said he was in the habit of using a solution of potassium permanganate and corrosive sublimate for filling the creases in the hands. It was important that the surgeon should frequently dip the hands in a disinfecting solution during operation. His own preference was for a *cold* solution of corrosive sublimate of a strength of one to two thousand.

Head.—The next most important source of infection was the hair of the head, because of the very frequent presence of dandruff, and even of street dust. The surgeon should wear a closely-fitting cap during operation.

Mouth.—It had long been believed that the expired air was sterile, and this was probably true with quiet breathing, but it was entirely different during conversation, as had been conclusively shown by bacteriological studies. It was obvious, therefore, that a gauze covering should be worn over the mouth, and if the surgeon would insist upon wearing a beard, this, also, should be covered. The operator should also refrain as far as possible from speaking while operating.

Dr. Frederick Holme Wiggin said that he had been deeply interested in the paper, which dealt with a most important subject, and one to which, ordinarily, not enough attention was given. He had been specially interested in the criticisms of the nail-cleaner, and had been accustomed, in his surgical practice, to clean his nails with the folded sterile towel. He thought it would be desirable, if practicable, for the surgeon to put on fresh underclothing after having taken a bath, as a preparation for operating. He was accustomed to cleanse the hands and arms by rubbing for several minutes with tincture of green soap and a stiff, sterile bristle brush. He was favorably impressed with the suggestion made in the paper of substituting sterile gauze for the nail-brush. Having cleansed the parts as just described, he washed with alcohol and again in an alcoholic solution of bichloride, 1 to 300. A final cleansing with sterile water was given. In prolonged operations he was in the habit of dipping the hands occasionally in an alcoholic solution of bichloride, and then in a sterile saline solution. The speaker said that the covering of the head with a cap was doubtless a good plan, but he had been content with protecting the brow with a scarf made of several layers of gauze. It was well to discourage conversation during operations, for it not only minimizes the danger of infection, but prevents the distraction of the operator from his work. He had never found it necessary to make use of any covering over the mouth.

Dr. Carl Beck said that the area of operation could never be absolutely sterilized, and it was a question whether this was necessary in practice, for it had been aptly said that there was no need of sending a policeman after every micrococcus. No matter how thoroughly the skin was cleaned, the follicles would still afford shelter to many microbes. No doubt catgut had often been erroneously accused of exciting infection when in reality the source of infection was the bacteria in the skin. The application of the tincture of iodine was a desirable method of combating skin infection. If the surgeon were attentive to his personal cleanliness, there should be no need for covering the mouth

Dr. M. W. Ware said that the objection to rubber gloves, founded on their promotion of sweating, was met by the substitution of cotton gloves. Experiments had shown that the hands under the cotton gloves were more nearly sterile than when under rubber gloves. It had been suggested that better disinfection of the hands would result from cleaning them under running water and discarding the basin.

Dr. Charles N. D. Jones advocated the heating of the glass operating table in a compartment, and the surgeon's taking a full bath to which some disinfectant is added, such as acetic acid and chloride of lime. He favored the dipping of the operator's hands in a disinfectant solution from time to time, and he sometimes made use, during operations, of a weak disinfectant solution, such as a 1–1,000 formalin solution.

Advantages of Rubber Gloves.—Dr. Joseph Wiener Jr., regretted that the rubber gloves had been, in this discussion, "damned with faint praise." Rubber gloves, he said, though introduced abroad, had been pretty generally discarded there. Dr. McBurney's enthusiastic advocacy of gloves had had much to do with their popularity in this country. He was satisfied that the hands could not be kept sterile during an operation without rubber gloves. The objections to the gloves had been well stated in the paper, yet he felt they were useful. He had begun their use about one year and a half ago, and, by persevering in their use, he found that most of the difficulties first experienced had vanished. This had been the experience of most other surgeons who had persisted in using them for two years. He would not think of doing any abdominal operation, any clean or any septic operation, without rubber gloves. He did not puncture the rubber gloves more than once in about fifteen operations, and found he could palpate fully as well as without the gloves. Lately they had found at the Mount Sinai Hospital that it was a great improvement to make use of dry sterile gloves well powdered with sterile talcum powder. Although he ordinarily perspired freely, he had been able, by the use of the talcum, to do an operation and keep the skin under the glove dry the whole time. This did away with one of the important objections to the gloves. Another great advantage of the gloves was that, while it would take fifteen minutes to disinfect the finger after handling pus, rubber gloves could be sterilized in as many seconds.

Dr. Robert T. Morris said that in this discussion the cell resistance of the person wearing the gloves had not been taken into consideration. The bacteria were not only in the follicles, but were also imbedded in the epithelial cells. If a person were strong and well, the bacteria would not be proliferating; on the other hand, if he were ill, as with an attack of tonsillitis, these bacteria would be found proliferating, and the fingers would ordinarily be moist. He did not think any young man could become a good operator by beginning with gloves, because of the interference with tactile sense, though no doubt one who had become expert in palpation might develop a good tactile sense after the persistent use of rubber gloves. Many surgeons found that they operated much more slowly with rubber gloves, and this disadvantage should not be overlooked. With regard to hand disinfection, he would say that good results were obtainable by the use of the nascent chlorine method advocated by Dr. R. F. Weir. Some of the depilatories composed of sulphites certainly did penetrate deeply into the hair follicles, and would destroy the bacteria in the epithelial cells. He had been impressed with this fact in connection with his work on animals, and he was experimenting, at the present time, in this field to discover a means of preparing the patient for operation. Blood serum was known to be distinctly germicidal, and it was a question whether it was not sufficiently so to make it unnecessary to dip the hands from time to time in a disinfectant solution while operating.

Dr. Fowler closed the discussion. He said that Dr. Wiggin's suggestion about the use of a gauze scarf on the forehead reminded him that he had omitted to mention in his paper the danger of infection from the dropping of perspiration upon the patient or into the wound. He had seen a drop of perspiration fall into a laparotomy wound, and had been present at the autopsy, and had felt that this death, like many other obscure ones, might well be attributed to infection arising from contamination with perspiration. Koeniger's bacteriological experiments showed plainly that not only was there infection of Petri dishes near by as a result of conversation but that this infection even extended to a considerable distance; hence it was well to enjoin silence upon all spectators at surgical clinics. More than ten years ago he had begun the practice of painting the skin with tincture of iodine before operation, and it was a particularly useful procedure in emergency operations. All that had been said about the interference of rubber gloves with the tactile sense could be applied to cotton gloves, though this should be done with fifty-fold more emphasis. In cleansing the hands it was very much more effective to scrub or scour the creases on the palmar and dorsal surfaces in the direction of these furrows, or across the hand. About nine years ago he had had constructed at St. Mary's Hospital an operating table in which a steam coil was placed underneath the table. He had used for many years the permanganate of potassium and bichloride solution, and one not familiar with this method would be surprised to find what a coating dried upon the hands after they had been dipped in it. This method had been suggested to him by some observations made many years ago by Lister himself. This surgeon found that in impregnating gauze with cyanide of zinc and mercury, when he used colored solutions, the penetration into the interstices of the gauze was very much greater than when a simple uncolored solution was used. Dr. Fowler said he had tried the chlorine method honestly and faithfully, and, while he had no doubt that it effected surface sterilization quite as well as, and perhaps better than, some other methods, he found that he and his assistants developed a troublesome eczema between the fingers, and hence it had become necessary to abandon this method. The occasional dipping of the hands into sublimate solution during operation would not, perhaps, thoroughly disinfect the skin, but its astringent action upon the latter imitated very closely that retractile effect which had been shown to be effective in postponing the passage of micro-organisms from the deeper parts to the surface of the skin Cold solutions had been found to be very much more effective in this respect than hot ones.

Treatment of Diseased Joints by Plaster Strapping.—Dr. F. R. Cook read this paper. He said that in 1893, and again in 1895, Dr. V. P. Gibney had published articles on the strapping of sprained ankles. The pathological conditions which responded most readily to strapping had one factor in common, *i. e.* relaxation of tissue. A relaxation of veins led to passive venous stasis with exudation into joints, tendons, and surrounding tissues, thus giving rise to swelling, pain, and more or less impairment of function of the joint. In chronic affections there might be a cellular hyperplasia leading to a connective tissue formation. Alternate hot and cold douches, with active and passive motion, were usually employed here. The good effect of strapping in sprains and contusions and stiffened joints following fractures or over-immobilization, was probably dependent upon the fact that this met the indications mentioned. It could be applied so as to act perfectly as a substitute for the sprained ligaments. This accounted for the ease with which the patients could walk about. In order to secure the full amount of benefit, the ordinary diagnosis of sprain was inadequate; one must determine not only what ligament or ligaments were involved, but where the ligaments had more than one insertion or function, as in the ankle, one must determine what special fasiculus or fasiculi were sprained. This diagnosis was usually made by ascertaining the position of the part when subjected to trauma, the position of the parts in rest and motion following the trauma, by determining the area of maximum tenderness and maximum local heat, and by comparing the amount of pain produced by forcing the parts into all of the extremes of motion of which the joint is capable. Strapping afforded protection, which was particularly useful in rheumatic joints. Sometimes it also gave rise, in sensitive persons, to considerable counter-irritation. The strapping also acted as a fomentation and as a means of securing pressure, and so limiting swelling. Strapping with the use of the parts was an excellent form of massage, and this he believed to be the most important function of strapping. The strapping, in cases of contusion, was applied with the parts relaxed, while in sprains, the strapping was done with the parts in closer approximation. A number of cases illustrating the prompt and decided relief afforded by this treatment were cited.

Dr. H. M. Silver said that he had strapped the ankle in many cases with great success. After its proper application, the patients could walk about, were usually free from pain, and had very little trouble afterward. He had had no experience with strapping the knee.

Dr. Charles N. D. Jones indorsed the method as an excellent means of practising auto-massage.

Dr. Cook, in closing, referred more in detail to the method of strapping. In the case of the ankle-joint, he was accustomed to use Gibney's method, except that he carried the straps obliquely instead of straight around the foot. In strapping the wrist-joint it was better to encircle the wrist, otherwise one did not get good support. Of course some care and experience were necessary to avoid excessive constriction. In this region he usually employed very narrow straps or adhesive plaster, and applied them over the wrist-joint in a figure-of-eight. Several methods were practised for strapping the knee-joint. Ordinarily, and especially when there was considerable exudation in the knee-joint, one strap should be carried around the joint at its center, so as to secure the necessary pressure. If more straps were used, they interfered with motion, which was what should be avoided. After the first strap the others were applied alternately above and below, just as in bandaging an elbow, and all of the straps met at the hamstring muscles and diverged. The first strapping would soon become relaxed and then reinforcing straps should be applied over this. In strapping the shoulder-joint it was best to carry the straps from the chest around the shoulder to the back, and then others above and below, just as in strapping the knee-joint.

The Economic Side of Smallpox.—An illustration of the loss and inconvenience which may be caused to a community by even a comparatively slight outbreak of smallpox is furnished by recent events in Barbados. That island is suffering from an outbreak of smallpox of a mild type. Yet the disease has already proved a serious incubus to the trade of the place, owing to the strict quarantine which has been imposed against it by the neighboring colonies, all the islands except Trinidad and the colony of British Guiana having prohibited the landing of any goods whatever coming from Barbados. The steamers have ceased to communicate directly with the shore, and boatmen, lightermen, and wharfmen are out of employment. Yet smallpox is the very type of a preventable disease.—*The Hospital.*

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held October 23, 1902

James N. West, M.D., Chairman.

Appendicitis and Pyosalpinx.—Dr. L. J. Ladinski presented two specimens to show the difficulty of diagnosis of pelvic disease. The first specimen, an appendix and pus tube, was taken from a woman of forty years, who had had nine children. Four days before admission to hospital she began to suffer from colicky pain, especially marked on the right side, and accompanied by vomiting, chills, and fever. The diagnosis was appendicitis, but further examination showed a right pyosalpinx. On operating he found both appendicitis and pyosalpinx. Apparently the two diseases were coincident. Pus was found not only around the vermiform appendix, between the coils of intestine, but also in the pelvis. The second specimen was one of double pyosalpinx and appendicitis, and in this case also he considered the two conditions were merely coincident. There was a rather long history of pain in the region of the appendix, with severe constitutional disturbance and pain about a week before admission. Examination showed an irregular hard mass on the right side, and the pelvis filled with an irregular, nodular mass, feeling much like a fibroid tumor. The complicating appendicitis was not considered at all in making the diagnosis. At operation a mass was found which consisted of intestine, pus tubes, uterus, and a very much enlarged and inflamed appendix. There was pus in the pelvis and between the coils of intestine as well as around the cæcum. Both of these patients made an uneventful recovery.

Ectopic Gestation Twice in the Same Woman.—Dr. H. C. Coe presented a specimen of ectopic gestation removed from a woman thirty-two years of age. She was seen in consultation in the latter part of May. The history was that three years before she had been operated upon for ruptured ectopic gestation, and that the left tube was removed. This statement was confirmed by the hospital records. When seen by him the woman had skipped two periods, and the colicky pains, the flow of blood, and other symptoms pointed to another ectopic gestation. A diagnosis to this effect was made and operation advised, but the patient refused. A week later, however, a posterior section was made for exploration. A ruptured tube was found on the right side with the ovary. The interesting point was that the left tube and ovary were still present and were found to be normal despite the hospital record of the first operation.

Dr. P. A Harris said, with regard to the recurrence of ectopic gestation in the same individual, that he had had four such cases.

Dr. Coe said he did not believe his patient had had an ectopic gestation the first time, and in this view he was supported by the pathologist who examined his specimen.

The Rontgen and Ultraviolet Rays in the Treatment of Uterine Cancer.—Dr. Margaret A. Cleaves presented this paper and reported a case (to appear in a future issue).

Dr. H. C. Coe said he had examined the patient very carefully before the treatment was begun, and there could be no question that the case would have been looked upon by surgeons generally as inoperable. He would not have attempted to use even the sharp spoon and curette. He had examined this patient again only yesterday, and the appearance was that of a woman shortly after a hysterectomy. No nodules could be felt at all on the right side; on the left side was an extensive cicatrix, the result of the malignant process. It had drawn the uterus over to one side of the pelvis. There was no longer any foul discharge. The appearance of the patient indicated a remarkable improvement, and he could not imagine that the same result could have been attained by any of the recognized surgical methods, not even the use of the galvano-cautery as employed so successfully by the late Dr. John Byrne. Personally he had not had a single case of malignant disease that he could consider cured; the disease had recurred in some cases six years or more after operation. There were several cases of uterine cancer under *x*-ray treatment at the hospital. In one of these, in the service of Dr. Jarman, of recurrent carcinoma of the cervix, in which it was not thought wise to operate again the *x*-ray treatment had been employed, and he understood that the disease had entirely disappeared. This case had been seen by a number of the surgeons, and there could be no question about the diagnosis.

Dr. **William James Morton** said that the case had been reported in the paper with great fidelity, and the author was to be congratulated. He hoped that in time the method of application would be simplified, and the number of treatments reduced. He personally believed that the treatment of such sases, as well as those of growths in the abdomen, could be effected in a simpler manner. He was in favor of the use of the *x*-ray alone. There was a certain pleasure in knowing just what does the work, and he objected strongly to mixing up methods, as it was both unscientific and unnecessary. It had been noted abroad that a certain type of cutaneous epithelioma—the nodulated, indurated type—yielded very slowly to the *x*-ray, yet these cases did better when the *x*-ray treatment was combined with the use of the Finsen light. This would seem to justify the author in the combined method which she had employed. A most important warning had been sounded in this paper with regard to throwing too rapidly into the system the toxins resulting from the disintegration of these growths. An operator could, according to his experience and judgment, make the *x*-ray treatment of cancer result in the development of sepsis, or he could produce a mummifying effect on the affected area. If the treatment were pushed too much it might cause the patient his or her life. The ordinary use of the *x*-rays three times a week he did not consider to be, as a rule, pushing the treatment too much. It seemed to him almost ridiculous to apply a local treatment with the *x*-ray to the disease on the supposition that it is a local disease; to his mind it was far more rational to treat the parts widely rather than confine the application of the *x*-ray to the mass or nodule that could be seen or felt. He knew of a case in which an intelligent surgeon had faithfully treated for two months with the *x*-ray a carcinoma of the breast in the neighborhood of the nipple, and while doing this had carefully screened off the adjacent parts. The result was that the tumor near the nipple improved very decidedly, but meanwhile the cancer extended into the lymphatics in the axilla. He could recall six cases of cancer of the uterus and rectum treated by means of the *x*-ray. One of them had yielded a remarkably good result. The patient had been brought to him from out of town, and the attending physician had remained with the patient for three weeks and had made daily examinations. This physician had previously removed the greater part of a recurrence of the disease by means of caustic, and on its recurring again had brought the patient for *x*-ray treatment. The local condition was very much the same as that described in the paper under discussion, but there was not the cachexia present in that case. His patient had been discharged as cured, and Dr. Bache Emmet had confirmed his statement that no evidence of the disease could then be found. He did not believe there was any necessity for the use of the internal tube, except in a case seen very early when there was reason to believe that the disease was strictly localized, and in such a case it might, perhaps, be better to excise the growth promptly, and then make use of the *x*-ray.

Dr. **George G. Hopkins** of Brooklyn referred to a case which had been carried in on a stretcher each day for a month. Several of the best men in Philadelphia had pronounced the case one of inoperable carcinoma. The patient was very anæmic and weak. The vagina was almost occluded, and projecting above was a grayish fungoid mass. After treating the case for six weeks he was able to introduce a seven-inch bivalve speculum, whereas [illegible] he had only been able to insert the speculum [illegible]. The treatment employed combined both the *x*-ray and the Finsen light. He thought we should be much more hopeful with regard to the treatment of uterine cancer than of cancer of the breast. The best German pathologists of the day had announced that the cancer cells of the breast were, as a rule, smaller than those of the uterus. The best pathologists of the day did not look upon it as a constitutional disease in its inception. The uterus was abundantly supplied with anastomosing lymphatic channels, and six or eight ducts discharge into the lumbar glands. These glands did not become involved until quite late in the disease, hence the treatment by either the *x*-ray or the Finsen light should prove most useful.

Dr. **A. D. Rockwell** cited a case in which a lupus had improved up to a certain point, under the Finsen light treatment abroad, and then there had been no further progress. On coming under his care he had made use of the *x*-ray treatment, and had readily succeeded in completing the cure. This case only suggested that the alternation of the *x*-ray and Finsen light treatment might be desirable in certain cases. He had never used the [illegible], and agreed with Dr. Morton that it was not necessary.

Dr. **James N. West** thought it was well to operate upon malignant growths as early as possible, and then subject them to the *x*-ray or the Finsen light. By operating first, the danger of throwing the toxins too freely into the system would be largely obviated. Those working in this new field should be most careful to have their diagnoses confirmed by microscopical examinations. He recalled one case in which he felt sure, from the clinical appearance, that the diagnosis was carcinoma of the cervix, yet, as a matter of routine, he had a microscopical examination made, and was surprised when the pathologist assured him that the case was non-malignant. This patient had done well, and had since born two children.

Dr. Cleaves, in closing, said that the idea of using the light was to employ the same vibrations, only in less degree, and so keep up the good influence. She thought in future the treatment could be applied less frequently and more simply with the same results. She did not favor the employment of the speculum, and agreed with the opinions expressed in the discussion to the effect that the tissues generally in the pelvis should be brought under the influence of the *x*-ray. With the Tesla tube the *x*-ray radiations were obtained not from one point, but from every part of the tube

The Indications for Trephining in the Cerebral Hemorrhage of Whooping-Cough.—Loewy says that the cerebral hemorrhages occurring in this disease sometimes fall within the jurisdiction of the surgeon. This is the case when there are pronounced symptoms of cerebral irritation and when the sudden appearance of the nervous disturbances point to extensive extradural ,subdural, or cortical hemorrhage. Under these conditions, so long as there are no distinct pressure symptoms, the pulse remains good, and the condition is not becoming steadily more serious it is preferable to wait. Hemorrhages, especially subdural, may be completely absorbed, and symptoms of circumscribed bleeding may be produced through capillary hemorrhages into the cortex, or simple œdema and even entirely negative autopsies are on record with such symptoms. If, on the other hand, the condition becomes aggravated, and especially if the pulse is that of intracranial pressure, trephining is indicated as in any other form of intra- or extradural hemorrhage. The longer the time that has elapsed since the onset of the symptoms, the less chance is there of operation being needed. Lumbar puncture is always indicated, and should be done early, since it is harmless, gives valuable diagnostic data and diminishes intracranial tension, if present.—*Deutsche Zeitschrift für Chirurgie.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 8, 1902:

	Cases.	Deaths.
Measles	51	1
Diphtheria and croup	318	46
Scarlet fever	93	9
Smallpox	4	1
Varicella	57	.
Tuberculosis	198	132
Typhoid fever	145	27
Cerebrospinal meningitis	..	1

Malaria in Ceylon.—Dr. Albert J. Chalmers, registrar to the Ceylon Medical College, says the *Lancet*, has made a preliminary report on the prevalence of malaria in Ceylon. The theory of the origin of the disease which is propounded by Mr. A. Perry, principal medical officer and inspector of hospitals, Ceylon, raises two points which are not without practical importance. They are: (1) Is it possible that the infection in man can take place by some other means than through the mosquito? and (2) If this be not possible, how did the cycle of the life of the parasite start? In reference to the causal relation existing between the climatic conditions and the incidence of the malady, Dr. Chalmers says: "There appears no doubt that the reason why so few anopheles, sometimes none, are seen in the dry season for months together—*e. g.*, in Accra and Kumassi, West Africa—and then the sudden appearance of these insects in numbers, is due to their hibernation in dark, protected spots. They come out again in the wet season, as this is the time *par excellence* when they find the pools of water with suitable algæ for propagating their species, and, in my opinion, this is the reason of the relationship between malaria and the rainfall."

The most interesting points which the report shows may be briefly summarized as follows: (1) Malaria, at the present time is epidemic in Ceylon only in certain localities; (2) The island contains many anopheletes, and the conditions which exist there are peculiarly suitable for their development; (3) A large proportion of the existing anopholetes are not infected with the malarial poison; and (4) Coolies affected with malaria are constantly being introduced from India to Ceylon. There is, therefore, a possibility that malaria may become more prevalent if these facts are not realized.

The Prognostic Value of the Ehrlich Diazo-reaction in Consumptives.—Gieseler gives the following improved formula for the reagents of this test. Instead of sulphanilic acid, paramidoacetophenon is used, as it gives more brilliant tints. Four c.c of reagent A (paramidoacetophenon 0.25; acid hydrochlor. 25.0; aq. dest. ad 500.0) are mixed with one-fiftieth of this amount (*i. e.* gtt. 1–2) of reagent B (sodium nitrite 0.5; distilled water 100.0) and shaken with 4 c.c of urine. One-eighth of the entire volume (*i. e.* 1 c.c) of ammonia is then added, and the color of the foam noted. The reaction is positive only when a distinct shade, varying from pink to deep red, is present. The reaction was studied in 100 patients, who were kept under observation for an average of four months. The result of these investigations showed that, though the reaction may be regarded as often affording useful corroborative evidence, still it cannot in any way invalidate conclusions derived from clinical observation. A positive diazo-reaction is simply a comparatively frequent phenomenon in cases ending fatally, but is not constant in its appearance, while, on the other hand, an existing reaction in cases not absolutely hopeless may disappear again if the condition improves.—*Zeitschrift fur Tuberculose und Heilstättenwesen*, Vol. 3, No. 5, 1902.

Indications that Our Methods of Fumigation Are Faulty.—G. E. Pfahler conducted experiments with formaldehyde gas on cultures of the staphyloccus pyogenes aureus taken from the surface of the floor, the bed, and the mantel; all grew well. With formalin used in different ways, all cultures grew. With sulphur thoroughly tried, all cultures grew with the exception of one, which remained sterile. The fact that we have been able to control epidemics by the use of the methods of fumigation would seem to depend more upon the customary cleansing given to infected rooms, etc., than upon the action of the gas. All investigators seem to agree that formaldehyde gas is the best disinfectant known, but we should aim at obtaining a more satisfactory method of application, which will probably mean an apparatus capable of generating the gas ten times as fast, or in more concentrated form.—*Proceedings of the Pathological Society of Philadelphia.*

Dengue Fever at the Civil Hospital, Hongkong.—The latest scourge afflicting Hongkong is dengue fever. The hospitals in the island have overflowed with patients of all ages and descriptions, and those not admitted for that disease have soon contracted it. Among the staff at the hospitals, the first to be attacked were the ward boys and native nurses, and in the last week of August seven of the sisters of the Government Civil Hospital were off duty with it, some in the initial stage, others convalescing.—*London Hospital.*

Health Report.—The following cases of smallpox yellow fever, cholera, and plague have been reported to the Surgeon-General U. S. Marine Hospital Service, during the week ending November 8, 1902:

REPEATED ECTOPIC GESTATION.

BY BROOKS H. WELLS, M.D.,
NEW YORK.
PROFESSOR OF GYNECOLOGY AT THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL; FELLOW OF THE AMERICAN GYNECOLOGICAL SOCIETY, THE NEW YORK ACADEMY OF MEDICINE, THE NEW YORK OBSTETRICAL SOCIETY, THE SOCIETY OF THE ALUMNI OF THE CITY HOSPITAL, ETC.

AN abdominal section for a ruptured ectopic pregnancy, an interval of a year and three days, a second section on the same patient and the removal of a second gravid tube, called my attention to the possible light to be thrown by the study of similar cases on the very obscure etiological conditions which may result in the arrest and implantation of the fertilized ovum in some portion of the Fallopian tube.

The record of my case is as follows:

Mrs. A. B., German, aged twenty-six years, had had one child when fourteen years of age, and had then remained sterile. There was no history of any pelvic inflammation or any history or local condition pointing toward a gonorrhœal infection at any time. On the evening of February 16, 1901, Dr. J. Y. Mangum was called to see her because of very severe colicky pains, from which she had suffered during the previous week. He found her with marked symptoms of internal hemorrhage, a mass to the right side of the uterus, and a history of irregular bleeding from the vagina for the previous month, and sent her at once to my service at the Polyclinic Hospital, with a diagnosis of ruptured ectopic gestation.

On admission at 10 P.M. her condition was very serious, and rapidly growing desperate. By 11, when I had reached the hospital and preparations were completed for the operation, the lips were white, she was pulseless at the wrist and semi-unconscious. Hot salt solution was thrown into the rectum, strychnia given hypodermically, and while an intravenous saline infusion was being made the abdomen was opened.

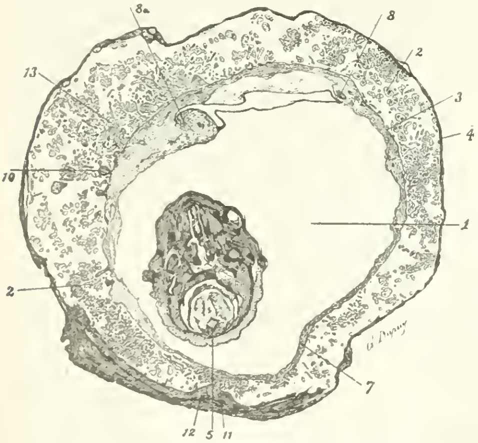
A large amount of fresh blood, some older clots, and an unruptured ovum the size of a large orange and of ten weeks' development were found free in the peritoneal cavity. The ovum had escaped from an extensive tear in the right tube. Active hemorrhage was going on from the torn ovarian artery.

The vessels were secured and the tube easily removed, there being only a few slight and recent adhesions binding it down. The appendages on the left side were free from adhesions, were apparently perfectly normal, and were not removed. The abdomen was closed in layers with slightly chromicised kangaroo tendon. The woman rallied well, made a smooth convalescence, and rapidly recovered from her extreme anæmia.

On February 17, 1902, Mrs. A. B. came again to the clinic, saying that she had gone over her time five weeks. She had spotted a little during the last two weeks, had had slight pain in her left side, thought she was pregnant, and wished to know if all was right. Bimanual examination revealed a tender, soft, semi-fluctuant, rounded mass the size of a hen's egg, lying close to the left of the uterus. The cervix felt soft. There was a slight, bright, bloody discharge. The body of the uterus was slightly enlarged and softer than normal. A large pulsating artery was felt to the left. A diagnosis of unruptured ectopic gestation was made, and the woman was at once sent to the ward and prepared for operation, though I wished to hold her over for my next clinic day, the 21st. On the 18th she complained of colicky pain for a short time in the afternoon. On the 19th, at about 11 A.M., a gentle bimanual examination was made by a member of the faculty. At 7 P.M. the house surgeon found signs of internal hemorrhage and a pulse of 136. These symptoms increasing, I operated at 9 P.M. Fresh free blood and some recent clots were found in the abdominal cavity. The blood was coming from eroded vessels in the wall of the left tube which enclosed an ovum of about eight weeks' growth. The tube was easily removed, the adhesions being recent and very slight. The abdomen was closed as before. Convalescence was smooth, the temperature never going above 99° F.

The specimen shows the tube of the left side distended by an oval mass one and a half by two inches in its diameters. This mass occupies the middle third, there being a small portion near the uterine end where the tubal mucosa is normal, and shows no microscopical changes, and a similar portion at the fimbriated extremity. After hardening and embedding, sections were cut at various planes perpendicularly to the tube length. The section from which the accompanying drawing was made, and which Dr. S. W. Bandler kindly examined for me, shows that the embedded ovum, which is about the size of a silver dollar, may be divided into two parts: An inner[1], the central cavity containing the fœtus, and an outer peripheral portion[2], comprised between the chorionic membrane[3] and the unbroken tube wall.[4] The fœtus evidences a well-formed neural cord with its canal.[5] A central vertebral formation, still in the state of cartilage, is present, evidencing two lateral prolongations, which surround three-fourths of the medullary canal. The age of the fœtus approximates about the eighth to the tenth week.

The central cavity is lined with a membrane[7] of considerable thickness, composed of a trabecular, branching, almost homogeneous network, in which are numerous spaces or vacuoles and numerous round or spindle-shaped cells with dark nucleus, often situated in the periphery of the spaces. The bodies of the cells are long and thin, uniting with each other, and forming together with numerous non-nucleating fibers of the same character the trabecular network. This inner lining evidences at various points in its circumference, but most essentially at a certain point, large spaces of oval shape,[8] lined by long flat cells, and filled entirely with very numerous, small, round, dark nuclei, whose protoplasm shows no boundary, so that the nuclei seem embedded in a homogeneous colorless substance, which is probably not protoplasm. These spaces filled with these round cells (fetal vessels filled with blood cells) are more numerous in an area situated near the thickest portion of this lining. In this thickest portion, are several of these spaces and two or three ducts, cut in transverse sections and lined with two or three parallel rows of small round cells, giving these ducts something of an epithelial appearance (allantois duct). This thickened area is apparently the point of insertion of the abdominal pedicle or cord.[8a]. At various points the peripheral layers of the inner lining take on the character of a fibrilated connective tissue. This inner lining is covered in its entire circumference by a membrane composed of a structureless protoplasm, in which are embedded small, round, dark nuclei, generally in two layers, and not infrequently in more (syncytium). This outer membrane is not closely adherent to the one before described, but is lifted off from it at almost all points of its circumference. It does not run an even, smooth course, but sinks into the larger and smaller depressions, covering the various projections and papillations. The typical structure of one of these projections or papillations[10] consists of a center of fibrillar connective tissue, which is an extension of the so-called myxomatous tissue, and a covering composed of the protoplasmic membrane, with its usual double row of small, round, dark cells. Into these projections there extend longer or shorter, but extremely narrow, spaces filled with the small, round cells or nuclei, found in the oval spaces. The oval spaces are blood vessels containing the early stages of the fetal blood, while the longer, narrower channels are capillary extensions of the same. The lining membrane plus its covering represents the chorionic membrane, and the papillations are simply extensions of the same, constituting practically and actually villi.



Section through gravid tube. Drawn from a photograph. × 2.

Between the chorionic membrane and the peripheral boundary of the ovum, in the entire circumference, are myriads of villi[2], connected, of course, with the chorionic membrane, but showing this connection at very few points. The older villi are composed of an inner filling of connective tissue, containing sometimes one, but generally several, large capillaries filled with round cells (fetal blood). Many of these capillaries are lined by a series of flat cells and surrounded by a parallel stratum of circular, thin fibers, with distinct nuclei. The outer surface of the villi is composed of protoplasm (homogeneous), in which is embedded a double row of small, round, very dark nuclei. Other villi are composed of a connective tissue center of a more myxomatous character and contain smaller capillaries, with a less distinct wall of circular fibers. These villi contain large cells, whose protoplasm is finally granulated, but whose small nucleus is extremely dark (nucleated red blood cells). At numerous points the change of these large nucleated cells to the smaller round cells situated in the capillaries may be distinctly observed. At the periphery of the villi, capillaries of a smaller caliber are extremely numerous. Many of the villi evidence at their tips a growth of small, round cells, densely grouped, often pushing the outer protoplasmic cover before them and constituting the so-called *cell groups*, which at numerous points pass over into the protoplasmic cover, or are themselves changed to smaller or larger protoplasmic multinuclear groups. Many larger and smaller pale nuclear masses are found free, or attached by a pedicle to the protoplasmic covering of the villi. At numerous points in the circumference of the ovum villi are attached to the tube wall. Here the cell groups at the tips of the villi furnish the point of contact and the round cells enter into and infiltrate the tube wall. In the major portion of the tubal circumference this condition is noted and the tube wall is extremely thin. At those points, however, where vessels and sinuses in the tube wall are still present, a perforation into them by the villi and the cell groups is evident. The tube wall is still intact in its entire circumference, and is lined at all points by either the infiltrating trophoblast cells or by large masses of fibrin.

The space between the chorionic membrane and the tube wall is of about the same width in the entire circumference. The villi fill up this space most completely at a point[11] near the location of the medullary canal of the fœtus, and the wall of the tube seems thickest at this point.[12] A differentiation into placental area and capsularis or reflexa does not exist, and is impossible, owing to the even division of the villi, but the area located near the medullary canal seems least invaded. Inasmuch as a point immediately on the opposite wall of the inner lining and near the abdominal surface of the fœtus proves to be the location of the abdominal pedicle insertion, this point[13] is the placental pole, and the former near the medullary canal is the summit of the ovum, and, as a matter of fact, the largest and the oldest villi are found at the placental pole.

We have here no division into placenta and reflexa, and no evidences of the union of a reflexa with the tube wall. There is no rest of tubal mucosa left, only an even growth of chorionic villi from every point of the circumference of the chorionic membrane, and an equally even invasion of the tube wall by trophoblast and villi in its entire circumference. Therefore the *placental sea* (intervillous space) is included between the entire tube wall[4] and the entire chorionic membrane[3] without any limitation to a *localized* intervillous space, so that an intervillous space existed in the entire circumference of the ovum. This ovum was evidently embedded at the summit of the tubal folds of mucosa; the villi developed evenly in the entire periphery of the ovum, destroying the mucosa folds very evenly, and invading the tube wall in a like manner. Because of this even invasion of the tube wall no perforations are to be found in this section, such as are usually or frequently found at this period in those tubal gestations in which a placenta develops at the point at which the ovum, at a very early period *comes in contact with the tube wall.* The specimen is in an excellent state of preservation and shows the relations in a perfect manner. No evidence of an amniotic membrane can be found and none lines the chorionic membrane.

The ninety-nine cases of repeated ectopic gestation in the accompanying table* are all that could be found by a search through the literature accessible at the library of the Academy of Medicine. In every instance but three the original reference has been looked up. The cases include all that could be authenticated from the lists of Varnier and Sens, Haret and recent journals. There are quite a number of cases recorded which have not been included in this table because of insufficient verification, some with no dates, no details, and no clinical or microscopic verification other than the writer's statement that they were cases of ectopic gestation. Thus Kyriac,[20] in a discussion on the treatment, merely refers to having seen extrauterine pregnancy occur twice in the same patient. This case is admitted by Haret to his statistics. Few of the cases are of much value in the present quest because of the lack of accurate information of the conditions found in the non-impregnated tube at the time of the first ectopic. They emphasize, however, the need of careful and accurate record of the remaining tube in all cases of ectopic pregnancy operated upon.

---

*This table will be published in the forthcoming volume of "American Gynecological Society Transactions."

In fifty-six of the cases which I have included in the table the diagnosis was verified by operation at the time of both the first and the second ectopic pregnancy, each patient thus undergoing two abdominal operations. Four of the women died, two from excessive loss of blood and two from septic infection.

In these cases the condition of the remaining tube at the time of the first operation was noted in twenty-one instances. Thirteen were apparently normal. Six showed slight adhesions. One showed slight catarrhal salpingitis. One was poorly developed and tortuous.

The intervals between the first and second ectopic are noted in eighty-three cases. The average interval was two years and four months; the shortest three months; the longest twelve years. Intrauterine pregnancy occurred between the ectopics in five instances, the time of impregnation running from eight months to five years after the first tubal implantation. Two of these pregnancies went to term, two aborted, and one became an hydatidiform mole.

Some curious cases are recorded of recurrence in the same tube. Thus N. G. Haydon[21] reports a case of "two fœtuses found in connection with the same tube," at an autopsy. They were in different portions of the same (right) tube. One was a recently ruptured sac, from which a three-months' fœtus escaped, and to this sac was attached a mass containing the bones of a mummified fœtus. The woman was supposed to have aborted about four years before her death, but no fœtus was then found. Tyler Smith and J. Braxton Hicks described this specimen of Haydon's. Bland Sutton[22] and also Varnier and Sens[23] regarded this case as doubtful. Stahl,[24] on the other hand, considers it authentic, as the chief cause for its rejection by others seems to have been the possibility that the uterus was bicornate, and it is hardly probable that if such a condition had existed it would not have been mentioned by such observers as Smith and Hicks.

Heinricius and Kolster[25] record a somewhat similar instance in a woman, aged thirty-three years at time of second extrauterine pregnancy; married. Six years before she had had amenorrhœa for six months, together with a movable abdominal tumor, which increased gradually in size. Menstruation then returned and tumor decreased in size until the fall of 1896. In 1897 it again enlarged until August, when it became smaller. Movements were felt in the tumor from April to August. On October 10 the cervix was dilated with laminaria tents and sounds. Death on the sixth day from septic peritonitis. The autopsy showed an unmacerated fœtus 51 c.m. long in a tumor connected with the left tube, and in another mass connected with this tumor were fetal bones, apparently those from the earlier pregnancy.

F. A. Stahl[24] saw a patient, twenty-five years old at time of first extrauterine pregnancy. Her menstrual and general history was normal. First pregnancy ended by normal labor (midwife) in November, 1893. History of pelveopara-perimetritis until seen by Stahl in July, 1897, with no other pregnancy in this interval. On November 20, menstruation was one week over time. She then passed what was probably decidua, then an irregular flow. An abdominal section on December 11 showed ruptured pregnancy in the ampulla of right tube; an ovum partially detached and adherent to fimbriæ was shelled out. Oozing from fimbriæ was controlled by folding them and stitching borders together, with the expectation that this would cause occlusion of tube. Retroflexion of the uterus was relieved by dissecting away a band posterior to it and performing an abdominal hysteropexy. She recovered with disappearance of dysmenorrhœa and other pelvic symptoms. Four months later the uterine attachment to abdominal wall broke down. She had vomiting, discharge from uterus, etc. Recovered. Was well until January 9, when she menstruated. There were symptoms of rupture of extrauterine pregnancy, March 25, 1899. Did heavy work for twelve days, then suffered a second attack of pain and syncope. Stahl was called April 9, and operated April 12. A six-weeks' ectopic was found at site of former pregnancy. The point of rupture was closed by blood clot, so there was no external hemorrhage. Tube and ovary removed. Recovery. September 21, 1899, cystic left ovary and part of tube removed. Recovery.

These cases show that, contrary to the opinion of J. Bland-Sutton[22] and others, extra-uterine pregnancy does not necessarily produce such gross changes in the tube as to prevent a second gestation in the same organ.

A number of other cases have been reported as recurrences of ectopic gestation in the same tube, but apparently without absolute proof. Varnier[26] for this reason discards those which have been described as instances of three extrauterine pregnancies in the same patient or as two in the same tube, by Haydon, Alban Doran, J. W. Taylor, T. F. Prewitt, Gottschalk, and Bennington.

Stahl[24] also rejects these cases, with the exception of that of Haydon, and also excludes one reported by P. A. Harris.[27] Harris made no record of the side upon which the first ectopic gestation occurred, though he thought that it was upon the same side as the second.

In the endeavor to find what is known concerning the etiology of ectopic gestation, a search through recent contributions to its literature shows a wide divergence of opinion and many conflicting theories.

While many still hold to the original dictum of Tait that a previous inflammation of the mucosa of the tube is necessary to allow the implantation of the ovum, some advance as efficient causes mechanical agencies, such as kinks, twists, tumors, etc., which may produce compression, partial obstruction of the tube and retardation of the ovum, while others cling to a theory of imperfect embryonic development of the ducts of Müller, or to a supposed atavistic condition of the tubal lining which permits of a "decidual reaction," or to changes in the ovum itself caused by the delay incidental to a "transmigration."

A brief recapitulation of accessible evidence may help us decide which of these alleged causes are entitled to bear the greater blame for the misplaced implantation of the ovum.

Mandl and Schmidt,[1] following others who had made similar experiments, attempted to arrest the ovum in the tube of a number of animals by ligation of the tube or uterine horn of one side. These attempts to imitate other forms of obstructive lesions failed to secure tubal pregnancies when the tube was ligated, while pregnancy did occur in the other horn. When the uterine horn was ligated, tubal pregnancy did not arise, but fœti were found in the portion of the uterine horn external to the ligature, and in the opposite horn. They therefore believe that a delay of the ovum in reaching the uterus is not the exclusive cause of tubal pregnancy, but that the tube must be capable of a decidual reaction, a peculiarity which is not always present. The delay of the ovum, which under this given condition of the tubal mucosa may lead to tubal pregnancy, may result from slow transmission of the ovum or from its external migration to the other tube. Referring to the negative results also obtained by Teinturier,[2] and his conclusion that it was necessary that there should be a previous disease of the tubal mucosa as well as a mechanical cause, Mandl and Schmidt state that it is as rational to believe that implantation of an ovum will occur more readily upon a diseased than upon a healthy tubal mucous membrane as to believe that pregnancy in the uterus is more likely to occur when endometritis is present than it is under normal conditions.

John Edgar,[3] noting the absence of tubal disease in a case of repeated ectopic gestation and in several ordinary cases of extrauterine pregnancy, concludes that tubal disease is not an essential cause of estopic gestation. He also thinks too much importance is attached to preceding sterility. Of twenty-six cases, which he has seen, nearly every one had had a child a few months or a year or two previously.

Herzog,[4] who has studied, microscopically, forty cases of extrauterine pregnancy, says: "Certain alleged causes formerly frequently cited as responsible for tubal pregnancy, such as inflammatory diseases of the uterus and tubes, must be absolutely discarded. We know now that these conditions, accused of being the cause of tubal pregnancy, make a woman sterile for the time being and, therefore, exclude tubal as well as normal uterine pregnancies. He ascribes a number of cases to conditions of the tubes due to anomalies in early embryonic development of the Müllerian ducts,[5] others to undue participation of the tubal mucosa in menstruation. He holds that the tubal mucous membrane normally undergoes slight changes during menstruation, and that when these are exaggerated they prepare the tube, as they normally do the uterus, to receive the ovum.

T. Carwardine,[6] says that the etiology is little known, but that inflammation of the tube is not the potent factor formerly supposed. In some cases it is a mechanical obstruction, *e. g.* myoma, polypus, or kink in the tube.

L. Seeligmann,[7] believes *traumatism* to be an important cause of ectopic gestation. In five cases which he mentions having seen there was a history of a fall or a blow in the pelvic region.

After a discussion of the views of other writers, and an analysis of forty-five cases of extrauterine pregnancy, Clitsch[8] summarizes his own opinion. He believes the cause of extrauterine gestation is not a single one. Usually there is a predisposition, inherited or acquired, leading to abnormal implantation of the ovum. Inflammation of the tube and its surroundings is the most common cause. Others—such as bursting of the tube, polypi, tumors, etc., which interfere with the lumen of the tube, and external or internal migration of the ovum to the other tube—are extremely rare. The cause of inflammation is usually an infection, which may be gonorrhœal, puerperal, or tuberculous. The most usual of these is the gonorrhœal. The final conclusion is that gonorrhœal inflammation of the tubes and their neighboring structures is the chief cause of extrauterine pregnancy.

E. Vignard[9] records thirteen cases of recurrent ectopic gestation. Ten of these had previously borne children. Eight had suffered from some genital disturbance, apparently inflammatory. Two had had irregular menstruation. One had had typhoid fever. From a study of these cases Vignard concludes that the tubal anomaly causing ectopic gestation is nearly always acquired. He does not attribute much importance to gonorrhœal infection but lays stress on *mild puerperal* infection as the great etiological factor. The unilaterality of the tubal lesions noted in many of the recurrent cases makes it difficult not to attribute *important etiological influences to inflammation caused by previous ectopic pregnancy* rather than that double salpingitis predisposes to bilateral ectopic.

Moericke[10] reviews the literature up to 1900, and discusses the various causes which have been advanced by different writers as etiological factors of extrauterine pregnancy. These are: pelviperitonitis, interstitial myoma, tubal diverticula and accessory tubes, interference of ova with each other, external migration of the ovum, reversed tubal peristalsis, abnormal trophic changes in the tube, infantile type of tube, salpingitis, especially gonorrhœal. He rejects all of these as causes of extrauterine pregnancy, and concludes that the human ovum does not embed itself in the tube unless there is some morphological or functional "dysteleology" of the tube. He considers tubal pregnancy as an atavistic manifestation, due to our unhappy social condition.

Goodrich[11] mentions as an objection to the inflammatory theory of the origin of tubal pregnancy the fact that the latter is not more often found with double pyosalpynx. His own explanation of this fact is that the reaction of the pus, whether acid or alkaline, may be of sufficient intensity to be incompatible with the life of the spermatozoon and possibly of the ovum, or that the inflammatory process furnished phagocytes in sufficient number to destroy either element. In support of the latter he quotes the experiments of Leopold[12] who found rapid absorption of fœti, introduced into the peritoneal cavity, only when there was peritonitis. Cases originating in a pus tube he explains by assuming that the process is old, the contents sterile, and phagocytes degenerated.

A recent compilation of the literature for the years 1896 to March, 1901, bearing upon the anatomy and etiology of tubal pregnancy is that of L. Aschoff.[13] It includes 320 bibliographical references. He remarks pointedly upon the poverty of the contributions in this field and their richness in numbers. He discusses the etiological theories under four heads:

1. *Atavism.*—Webster's theory is one which recent investigations have absolutely disproven. Aschoff believes that an ovum can only become implanted in a tube when the latter happens to possess the capability of a decidual reaction. He considers this an atavistic property. Aside from the fact that tubal pregnancy is rare in animals, the theory fails to hold because the capability of the tube for producing a decidua for embedding the

ovum is entirely unnecessary and in most cases does not exist. Patellani,[14] without considering the anotomical difference between tube and uterus, compares the functions of the oviducts of amphibians and birds, which, however, also contain the "Eihüllen" (egg sheaths?), with those of the *Müllerian* ducts of mammalia, likening the infantile, undeveloped human tubes to the cornua of the human uteri. He concludes that tubal pregnancies show a dysteleological functional condition just as developmental anomalies of the female sexual organs show a dysteleological morphological condition—a reversion to an earlier state.

Aschoff also criticizes Moericke[10] for seeing the weakness of the hypothesis of Webster and Patellani, yet himself reaching the conclusion that the ovum can become embedded in the tube only when a morphological or functional dysteleology exists.

2. *Functional Disturbances of the Tube through Inflammation and Atrophy.*—Chief among these is inflammation, particularly gonorrhœal. Recent anatomical investigations show that it is immaterial whether the tube is inflamed or not, as far as the possibility of the ovum becoming embedded is concerned, just as this may occur in an inflamed uterus, though inflammation increases the chance of abortion. Writers vary greatly in histological conclusions. Dührssen and Grossmann found small cell infiltration and loss of cilia, especially in the uterine portion of the tube, while Paguy, Fieux, Martin, Kreisch, and Thomson could discover no signs of inflammation. Mandl found that even in uterine pregnancy there is a rich round-cell infiltration of the tube wall, so care must be taken in diagnosing the presence of inflammation of the tube. Many writers support and many oppose the inflammation theory as the cause of tubal pregnancy. Its strongest support lies in clinical histories of previous endometritis after abortion, peri- and parametritis, gonorrhœa, and prolonged sterility before tubal pregnancy. On the other hand, there have often been normal births before the tubal pregnancy and no new gonorrhœal infection since their occurrence, and the existence of old gonorrhœal infection does not seem compatible with such numerous normal pregnancies. Many adhesions of the pregnant tube are the result of the pregnancy or of hemorrhage caused by it, not of an old inflammation. Marked inflammation of the non-gravid tube strongly supports the idea of previous disease of the appendages, but does not conclusively prove that the pregnant tube was also so involved. Local tuberculosis has sometimes been found.

Taylor and Dührssen are strong supporters of the theory that puerperal involution of the tubes leading to their marked atrophy is an important cause of tubal pregnancy. Heuer and Doktor attribute great importance to this puerperal or lactation atrophy.

3. *Mechanical Obstacles*—kinking of the tube by bands, polypi in lumen of the tube, diverticula, etc. The experiments of Lataste, Teinturier, Mandl, and Schmidt, who attempted to arrest the fertilized ovum in its passage to the uterus by ligation of the tube, all failed, and what would have been the strong support of the mechanical theory was thus lost. There are certainly cases in which neither inflammatory lesions nor obstructions exist.

4. *Abnormalities of the Ovum and of Its Transmission.*—In this group are included cases reported as external migration of the ovum through the peritoneal cavity to the other tube. It is also possible that the fertilized ovum moves abnormally slowly, or too rapidly undergoes processes of development. Pathological lesions of the ovaries are held by some to be responsible for such abnormal conduct of the ova.

In conclusion, Aschoff holds that until more is known in regard to the manner, time, and place of normal impregnation and development of the ovum, we can expect to know little of the causes of its slow movement or rapid development.

Petersen[15] states that all investigations show that ectopic gestation occurs most frequently in those who have previously borne children, and those who have remained sterile for a long time before the tubal pregnancy and had had genital, particularly tubal disease.

He holds that, as observers differ as to whether the salpingitis so often observed is the primary cause of ectopic gestation or secondary to it, histological examinations must decide the point.

Dührssen[16] studied cases with a view to determining, from the distribution and intensity in various parts of the tube of a catarrhal process, whether this process arose independently of the ectopic gestation and before it, and so might bear a causal relation, or was secondary to it. The lesions were found to diminish as one passed from the uterine end of the tube toward the site of the tubal pregnancy.

Engström[17] examined five cases of tubal pregnancy situated at the isthmus, and found in all signs of catarrhal salpingitis on the side toward the uterus, while if they were present on the other side of the site of attachment of the ovum they were less intense than in the former region. The variation in intensity of the lesion in passing from one portion of the tube to another was not investigated, as in Dührssen's examinations.

Petersen's series consisted of fourteen cases of tubal pregnancy from the middle of the second to the end of the fourth month, except one of about two weeks. In twelve of these, symptoms or signs of salpingitic disease were found. To study the variation in intensity of the lesion, transverse sections were taken at intervals of ½ to 1 c.m. throughout the entire length of the tube, and in many serial sections were made at chosen portions.

In the six cases of tubal pregnancy at the isthmus the ovum was attached at the middle of the tube, except in one case in which it was 3 to 4 c.m. from the os abdominale. In the uterine portion was a mild catarrhal process, which diminished in intensity in the direction of the dilated portion of the tube. Where the mole was situated there were sometimes changes due to pressure and dilatation, otherwise this portion was normal or nearly so. The ampullar portion was normal. In six other cases the ovum was in the ampulla. In these also the catarrhal process diminished from the uterine end outward. In two cases there was even some normal mucosa close to the point of attachment of the ovum on its uterine side; in one case it was nearly normal at the placental attachment; in three cases there was a slight catarrhal change in the neighboring mucosa.

In nine cases the non-gravid tube was also examined and a similar catarrhal condition found.

Existence of such a process in the unimpregnated as well as in the gravid tube, and the progressive diminution in intensity of process from uterus outward, with comparatively normal conditions of site of attachment of the ovum and the portion of the tube external to this, point strongly to an ascending infection from the uterus as the cause of the salpingitis. This evidence of extension from the uterus, the bilaterality of the lesion, which is of a chronic character, and often too far advanced to have originated after the fertilization of the ovum, and the frequent association of salpingitis with extrauterine gestation, indicate that the tubal lesion antedates the tubal pregnancy.

In two cases there were no signs of salpingitis. In one of these the tube twisted four times, evidently a congenital anomaly; in the other the only lesion was a fatty deposit between the layers of muscle directly opposite the point of attachment of the ovum, which might have interfered with the tubal peristalsis at that particular part of the tube. The material studied does not give definite evidence in answer to the question whether the ovum can be implanted on an abnormal mucous membrane, though in one case decidual formation was found in both tubes not only in normal, but in catarrhal mucosa. Seven of eight cases studied for the purpose showed distinct evidence of the formation of a capsular membrane. At the point of attachment the tube wall was usually thinned, the ovum being directly on the muscle layers. A decidua-like transformation of the cells of Langhan's layer was frequent. Distinct decidual cells were found at the point of implantation in only one case; in three they were found in the capsular membrane. In only two cases were decidual cells found in a part of the mucous membrane not surrounding the ovum.

An important contribution and one well worth attention is that of A. Couvelaire[18], who, after careful study by methodical section of fourteen tubes, three containing uninjured ova, finds that at a short distance from the ovum the tubal mucosa shows little change beyond increased vascularity and slight swelling, the epithelium remaining intact. At the site of the ovum itself the tube becomes thickened by hypertrophy of its muscular fibers and connective tissue. The mucosa shows at first an intact epithelium, is thickened by cellular hyperplasia, and contains groups of large, pale polyhydral cells, the so-called decidual cells of the tube. The tube of the opposite side in two cases which were examined gave no evidence of the "gravid reaction" of Webster. By the end of the fourth week the epithelium over the area of insertion of the ovum has disappeared, but no layer comparable to the spongy uterine decidua can be distinguished. The intravillous space of the embryo is separated from the tube wall by a layer of cellular elements, arranged as a fibrinous capsule. This external capsule he believes to be composed entirely of fetal elements. The tubal wall under this "capsule" shows extreme leucocyte infiltration.

As the result of a similar method of investigation, Cornil and Weinberg[19] arrive at an almost opposite conclusion. They hold that the external covering of the ovum is formed exactly as is the uterine decidua reflexa by the mucosa of the tube growing around and enveloping the ovum, and that the covering of the ovum is exactly like that of the lumen of the tube into which it projects.

In a most scholarly and exhaustive paper, recently published in the *Journal of Obstetrics*, L. W. Bandler goes minutely into the histology of the ectopic ovum and tube. He proves, as an histological fact, that in tubal gestation no decidua or trophospongea develops. This view is further strengthened by the fact that the tubal mucosa is not, like the lining of the uterus, a lymphoid tissue. As regards the processes depending on and originating in the ovum, they are the same in both uterus and tube.

From a study of the material we have reviewed, one may formulate the following conclusions:

Recurrent ectopic gestation is not extremely rare, and may be expected in a large proportion of pregnancies that occur subsequent to a tubal implantation of the ovum.

We are not justified in taking out the remaining and apparently normal tube at the first operation. Yet the fact that recurrence is liable to occur makes it necessary to watch with unusual care the early progress of any subsequent pregnancy.

Most reports of recurrent ectopic pregnancy have been so wanting in detail as to be of only slight value for purposes of study. For the sake of possible light to be thrown on the etiology, operators should make careful written records of the conditions found in the remaining tube at any operation for ectopic gestation, and should submit the specimen itself to competent pathological examination. They should also record cases of normal pregnancy occurring subsequent to ectopic gestation.

It is probable that the most frequent etiological factor leading to the abnormal implantation of the ovum is a mild infection of the tube, which, causing a change in its epithelial lining, increases the time occupied in the passage of the fertilized ovum through the tube.

TYPHOID FEVER, SYMPTOMATOLOGY, AND CLINICAL DIAGNOSIS.*

By CHARLES E. NAMMACK, M.D.,
NEW YORK.
PROFESSOR OF CLINICAL MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE; VISITING PHYSICIAN TO BELLEVUE HOSPITAL, NEW YORK.

Typhoid fever is an old subject, but, like the kaleidoscope, perhaps, we can shake it up again this evening and form new mental pictures, especially since its symptomatology is so complex. We are accustomed to regard typhoid fever from the standpoint of its intestinal lesions, yet typhoid fever is no more primarily intestinal than is smallpox primarily a cutaneous disease.[1] Cases may be grouped as follows: (1) Ordinary typhoid fever with marked enteric lesions. This includes the immense majority of all cases. (2) Typhoid septicæmia, a general infection with the bacilli without special local manifestations. At the bedside these cases present the picture of a severe intoxication with high fever and delirium. (3) Typhoid fever with localizations other than enteric. Clinically, the typhoid fever will be masked by the predominance of symptoms referable to the lungs, kidneys, meninges, or spleen. (4) Mixed infections. Not double infections, as with the bacillus tuberculosis, the diphtheria bacillus, or the plasmodia of Laveran, but conditions induced by one organism which favor the growth of other pathogenic forms, thus causing secondary infection with the colon bacillus, the streptococcus, staphylococcus, or the pneumococcus.

It is quite impossible within the limits of this paper, and of your patience, even to enumerate the long list of symptoms attending the progress of a disease having so wide a scope. He who studies typhoid fever attentively will not only gain an intimate knowledge of the working of any acute infection introduced into the human body, but he will gain also a thorough insight into the sanitary intelligence of the community in which he is living. The bacillus of Eberth is constantly present in the lesions, and it is discharged in the stools, urine, vomitus, sputum, and sweat. Widely distributed in the body, it has wide capacity for mischief outside the body after its discharge, and its conveyance by actual contact, by infection of water, by infection of food, and by contamination of soil, must be carefully guarded against. The recent paper by M. A. Veeder[2], on typhoid fever from sources other than water supply, is timely and significant. It gives us a clue to the explanation of the remarkable state of affairs existing in Jacksonville, Fla., during August and September, 1898. Thirty thousand civilians inhabited that city, and the same number of soldiers were encamped near by. Both civilians and soldiers drank water from the same source. Among the civilians there were only a few sporadic cases of typhoid fever. Among the soldiers, over sixty were admitted to the division hospitals each day[3].

In whatever way the bacillus typhosus is introduced, we have the onset of the disease after an incubation period ranging from four to twenty-one days. The onset is commonly insidious, and the actual time of beginning of the disease in ordinary cases must be fixed by the day the patient takes to bed. Rarely is the onset abrupt, but the practitioner will be on his guard in cases of sudden fever marked by decided symptoms of a gastrointestinal type or catarrhal type, especially when associated with disproportionate slowness of the pulse, pronounced and persistent anorexia, epigastric tenderness, and splenic enlargement[4]. During the first week the temperature may have the characteristic "step-like" rise, but this is by no means invariable, and too much diagnostic stress should not be laid upon its absence.

The prominent features of this week are the nervous symptoms, *i. e.* headache, mental confusion, wandering at night, but no actual delirium. Diarrhœa is usual, but constipation may exist and, indeed, prevail throughout the disease. Cough and bronchitic symptoms are not uncommon. Toward the end of the week the characteristic splenic enlargement and rose-colored rash are manifest.

In the second week the foregoing symptoms persist, and, with the exception of headache, are aggravated. Defervescence may now occur in the mild and favorable cases.

In the third week the symptoms are the same, but more grave. Loss of flesh becomes marked. There is danger of pulmonary complications, of failure of the circulation, and special danger of perforation and hemorrhage.

In the fourth week all symptoms ameliorate and gradual improvement takes place, except in severe cases, when the fourth and even the fifth week may present an aggravated picture of the third.

In the fifth and sixth weeks occur many of the complications and sequelæ. This sketch of the regular course of the disease may be tiresome and unnecessary to this audience, but will serve as a prelude to our consideration of the special features and symptoms which have diagnostic value.

The rash is the most valuable single sign. When associated with the characteristic fever, and with enlargement of the spleen, the combination forms a diagnostic triad which can be relied upon with considerable certainty. The absence of leucocytosis and the presence of Ehrlich's diazo-reaction furnish valuable accessories. When to these can be added the demonstration of the Widal reaction, the confirmation is complete. But this happy combination does not exist early in the disease, and may be absent altogether. The rash does not appear until the seventh to tenth day, is not invariably present, may be very sparse, and is often accompanied by other skin eruptions which confuse the picture. Departures from the type of the fever curve frequently occur. That such a thing as a febrile typhoid exists has been called to the attention of the profession by Liebermeister[5]. The temperature in typhoid fever, however usually gives us valuable indications in diagnosis, prognosis, and treatment. The splenic enlargement occurs in more than 90 per cent. of cases, is apparent at the end of the first week, and lasts until the fourth week, but is also found in so many diseases other than typhoid fever, that, save as one leg of the tripod, it has not much value. The absence of leucocytosis in a suspected case may be of decided value, but since leucocytosis is also absent in other diseases for which typhoid fever may be mistaken, it lacks decisiveness. Differential counts of the leucocytes are said to have much value both in diagnosis and prognosis. The exhaustive studies of the blood in typhoid fever, made at Johns Hopkins Hospital by Thayer and others, have added much to our bacteriological knowledge of the disease. Happy, indeed, must be the practitioner who can avail himself of the ready, rapid, and certain demonstration of the Eberth bacillus during every period of the disease. This ideal method of diagnosis is, as yet, however, restricted to the experienced bacteriologist. The method of serum diagnosis, known as the Widal reaction, has come into almost universal use, and is a valuable aid, but notwithstanding its importance, careful observation at the bedside must still take first rank, and no perfection of laboratory method can supplant the painstaking study of a skilled clinician[7]. The bedside diagnosis presents but little difficulty in a typical case, which can be observed for a considerable time. At the outset, though, the picture presented is that of an acute infectious disease, without positive differentiating features which would enable one to decide at once between typhoid fever, cerebrospinal fever, and acute miliary tuberculosis. I once had an opportunity to present these diseases in adjoining beds in Bellevue Hospital, and to teach their differential signs with the help of the table shown herewith:

---

*Read before the New York Academy of Medicine, Section on General Medicine, October 21, 1902.

	ACUTE MILIARY TUBERCULOSIS.	ENTERIC FEVER.	CEREBROSPINAL FEVER.
Respirations .	More frequent.	In normal ratio.	Irregular.
Abdomen. . . .	Flat, often scaphoid.	Tympany.	Not distinctive.
Diarrhœa. . . .	When present, of certain character.	Common, and different in character.	Constipation usual.
Temperature.	Extremely irregular.	Of definite type.	Less definite.
Nosebleed . . .	Rare or absent.	Frequent.	Not common.
Splenic enlargement.	Not early nor marked.	Frequent.	Not marked.
Headache . . .	Acute.	Dull.	Pronounced and severe.
Photophobia .	Frequent and notable.	Rare and not well marked.	Intense.
Phonophobia	Frequent and notable.	Rare and not well marked,	Extreme.
Vomiting	Common and persistent.	Much less common.	More frequent.
Convulsions .	Frequent.	Rare.	Usual.
Delirium.	Alternates with headache.	Headache ceases on appearance	Not limited to first stage.
Rose spots. . .	Absent	At end of first week.	Wanting.
Other eruptions present	Petechiæ	Sudamina.	Petechiæ purpura herpes-labialis.
Widal's reaction	Wanting.	70 per cent First week 80 per cent S'c'd week 90 per cent Third week	Wanting.
Tubbing .	Marked drop in temperature	Not more than 2° rectal.	Provokes muscular spasm. Hot baths indicated, if any.
Invasion .	Gradual generally.	Gradual.	Abrupt.
Hyperæsthesia	Not marked.	Of brief duration.	Intense and general.
Retraction of neck . . .	Wanting	Wanting in usual form.	Present.
Ophthalmoscope. . . .	Tubercles in choroid (?)	Negative.	Papillitis early blindness late.
Kernig's sign	Present in tuberculous meningitis	Absent.	Present.
Lumbar puncture . .	Sterile in tuberculous meningitis	Usually negative.	Meningococcus, in all.
Leucocytosis .	Usually from suppurating focus	Absent.	Present.

This table must, of course, be taken as descriptive of typical cases of each disease, the kind that are found to perfection only in the textbooks. Even the roseolous exanthem, that most reliable sheet-anchor in our bedside diagnosis, has been wonderfully counterfeited in acute miliary tuberculosis and in cerebrospinal meningitis.

The instances are extremely rare, but have been reported by reliable observers.

It is not, however, with regard to these two comparatively rare diseases that mistakes in the diagnosis of typhoid fever are most frequently made. The experience of the Spanish-American War conclusively proved that the term malaria covers a multitude of diagnostic sins. There is one absolute pathognomonic sign for the diagnosis of malaria, and that is the demonstration of the plasmodium of Laveran. If that demonstration were made oftener there would be fewer cases of "malaria," "bilious remittent," and "typho-malarial fever" recorded in this latitude, and more cases of typhoid fever would be recognized, more ambulatory patients put to bed, and more deaths from intestinal perforation avoided. Here is an instance in which a simple microscopic demonstration outranks any amount of bedside theorizing.

Up to the middle of the nineteenth century typhus fever was not properly distinguished from enteric fever. At the present time, and in this city, the differentiation is rarely called for, and need not detain us to-night. Other diseases, which have been mistaken for typhoid fever frequently, but which, on careful study, present distinctive characters, are children's exanthems, influenza, appendicitis, peritonitis, trichinosis, enterocolitis, pneumonia, pyæmia, and other septic processes, ulcerative endocarditis, and secondary syphilis.

The bacteriological diagnosis of typhoid fever does not come within the scope of this paper, but has been assigned to other hands. Bacteriology has led us to the recognition of diseases presenting the clinical picture of typhoid fever, but which, as demonstrated by blood cultures and agglutination test, are probably caused not by the typhoid-bacillus, but by closely related organisms, the so-called paracolon or paratyphoid bacilli. Recent work in the differentiation of bacillus typhosus from bacillus coli, and other bacilli intermediate between the typhoid and colon groups, has been done by Widal and Schottmuller abroad, and by Gwyn and Cushing in our own country[8]. From the clinical side, paratyphoid infection has been described by Brill[6], Meltzer,[9] and others.[10, 11, 12, 13] It is probable, however, that the differentiation of these various bacilli will prove to be of bacteriological, rather than clinical, interest, and that the term typhoid fever will still be understood to cover infection from any of the group of intermediate bacilli, just as the term abscess comprehends collections of pus from various causative agents.[12]

MONOPLEGIA DISTURBANCES OF SENSIBILITY IN CORTICAL PARALYSIS.*

By SOL G. KAHN, M.D.,
LEADVILLE, COL.

M. R., a NATIVE of Austria, aged thirty-three years, strong and robust, who has never been sick, except from occasional attacks of lead-colic, due to inhalation and absorption of fumes from the smelter in which he is employed, left home for work at the usual time, 6 P.M., on December 29, 1901. He was employed as a furnace man at the Arkansas Valley plant of the American Smelting and Refining Company.

About 8 P.M. two men were handling a pot of slag, which was partly cooled and considered sufficiently cold to remove to another part of the works. They had the slag on an elevated platform, about twenty feet above the ground and fifty feet away from where R—— was working, when the slag exploded, and a piece came down upon his head, knocking him down and rendering him unconscious.

He was picked up and removed to his home. His head was covered with blood, and his left arm was limp. He was able to walk with assistance, and directed the removal of his clothing.

I was sent for, and reached the house about 10 P.M. Upon examining his arm I found it was not broken, but paralyzed, and that he had no sensation from the tips of the fingers to the shoulder, inclusive.

Upon examining his head for the cause of the blood upon it, I found a depressed fracture of the right parietal bone. The wound upon the head was giving him no pain or inconvenience, and, as it was 10.30 P.M., and I would be compelled to operate by lamp and candle light, I decided to put on a wet dressing until morning and operate by daylight.

I shaved his head around the wound, and put on a 1-10,000 corrosive sublimate dressing.

The following morning, after careful examination, I found, upon drawing a line from occipital protuberance to glabella, a distance of fourteen inches, and taking the central point, or seven inches, the edge of the wound was two inches to the right, and three inches above, the right external auditory meatus. The length of the wound was two inches, and the transverse diameter one and one-half inches.

The patient's head was entirely shaved, and every precaution taken for an aseptic operation. The operation was performed at the home of the patient, a small three-room cottage. The gowns, dressings, gauze, sponges, towels, and instruments were all sterilized upon the kitchen stove in a portable Boeckmann sterilizer. After everything was in readiness, Dr. A. J. McDonald gave the anæsthetic, and Dr. J. H. Cole assisted in the operation.

Upon raising the flaps and examining the wound, we found fragments of the bone had penetrated the dura mater, the arachnoid and piamater, and lacerated the cortex. There were also some pieces of slag lying upon the cortex. After carefully removing all fragments of bone and slag, also the depressed pieces of bone, smoothing the edge of the wound and washing with sterile normal salt solution, the wound was packed with borated gauze, and a sterile dressing was put on, which remained for five days.

The man made an uneventful recovery, as far as the wound was concerned, never having any increase of temperature or acceleration of pulse, but the left arm did not do so well. With the removal of the pressure from the motor area of the brain I expected the paralysis gradually to improve. It did not meet my expectation. Upon a careful examination it was found that R—— had not alone loss of motion, but also loss of sensation of the entire left arm, hand, and side, down to the lumbar region. The area involved was from the median line in front to the spinal column behind.

About ten days after the injury, slight clonic spasms were noticeable over the paralyzed area, lasting only a few seconds. They did not come on with any regularity or to the same degree, frequently two or three days elapsing between them.

Eight months have elapsed since the injury, and the twitchings are still noticeable, but the frequency and extent have materially diminished. There was at no time any atrophy of the paralyzed muscles apparent. About thirty days after the injury movements of the arm commenced to be noticeable. Power in the hand has not fully returned, though it has improved to a great extent.

On March 6, 1902, Dr. Geo. L. Porter of Bridgeport, Conn., examined Mr. R——, and, by the pin-test, could not elicit any sensation below the wrist, although there was some strength and very slight movement of the hand and fingers.

This is a case of traumatic monoplegia, and interesting because we had complete anæsthesia of the paralyzed limb and left side of the trunk.

"Pepper's System of Practical Medicine," p. 44, Vol. V, edition of 1886, says: "Monoplegia, or paralysis of one extremity or of one side of the face, is not rarely observed. It may be caused by central lesions in the brain or spinal cord, or by an affection of the nerve-trunks of the part. Cerebral monoplegias are of great importance in diagnosis, and may be distinguished from others by: (1) Loss of power is greatest in the distal part of the affected member; (2) The precedence or coincidence of spasms (usually clonic or epileptiform) in the limb; (3) The absence of marked anæsthesia; (4) The preservation of muscular nutrition."

Strümpell, in his textbook on medicine, edition of 1901, page 1074, says: "A disturbance of sensation would invariably accompany cortical paralysis in man, but about this point clinical observations do not yet give perfectly harmonious results."

In our case there was, without doubt, a lesion of the motor area in the region of the anterior and posterior central convolutions. And, as the wound in the skull shows, the lesion was over the center for motion of the upper extremity. We had not alone paralysis, but also an anæsthesia of the paralzyed limb.

This case demonstrates the correctness of that view of observers, that the motor area of the brain cortex is also the center for skin sensibility of the same part.

Professor Obersteiner, in his book "Bau der Nervösen Centralorgane," fourth edition, Vienna, 1901, page 134, says:

"Our knowledge of localization of skin sensibility on the surface of the cortex of the brain is not well established. The general belief is that the parts of the brain cortex which give nerve force to certain specified groups of muscles are at the same time the center of cutaneous sensibility for the muscles and the skin covering them. This view is not, however, sufficiently established by clinical observation, because *crossed cortical paralyses are often not accompanied by the loss of sensibility*. Brissaud explains this fact by asserting that each hemisphere receives tactile impressions from both sides of the body; according to his view, the sensitive tract splits in the semiovale and part goes to the cortex and the rest finds its way through the splenium corporis to the corresponding part of the cortex of the opposite hemisphere. Charcot and Pitres believe the disturbances of the sensibility observed in one-third of the cortical paralyses are of purely functional origin, and are analogous to hysterical anæsthesia."

---

*Read at the Rocky Mountain Interstate Medical Association meeting, Cheyenne, Wyo., September 9, 1902.

Strümpell, page 1074, says: "About the condition of sensation when there is cortical paralysis we know as yet very little. The experimental researches of Munk and the anatomical investigations of Flechsig, and others, have led to the conclusion that the termination of the sensory tract of the lemniscus, the so-called sensory sphere, is, in part, in the same cortical region as the motor cortical centers."

Our case, from the clinical standpoint, demonstrates the correctness of the above-named anatomical and physiological investigations. The view of Charcot and Pitres that the disturbance of the sensibility observed in cortical paralysis are of functional origin, and are similar to hysterical anæsthesia, was not absolutely borne out, as our patient had never any manifestations of hysteria.

This case is also remarkable in another respect; namely, there was an anæsthesia of the left side of the trunk, which demonstrates that there was a lesion of the center for the trunk as well as the center for the upper extremity. The motor area for the trunk lies in the superior frontal convolution, near lobulus pracentralis. This area was also injured, and the observation of this case demonstrates that the center for sensation of the trunk must be located in the same area as the motor area—that is, in the superior frontal convolution.

In conclusion, I will repeat that the clinical observation of this case shows that cerebral paralyses (monoplegias), due to lesions of the motor area of the cortex, are also accompanied by loss of sensibility, and that both motor and sensory areas must be located in the same place.

What explanation can we give for some observers having found motor paralysis without loss of sensation, and others having found both paralysis and loss of sensation? I believe that the extent of the injury has much to do with it. Both areas appear to be in one place, but on different planes. If the injury is slight and the contused or lacerated area of the cortex is only superficial, we may have paralysis without anæsthesia, but if the injury is more severe, and the deeper cortical cells are disturbed, we have both paralysis and loss of sensation.

The anatomical investigations of Meynert show that the brain cortex consists of five strata, and each stratum has a special histological structure. Without doubt the physiological function of one stratum serves for motor purposes, one for sensation, and so on. This view is not a new one, for Church and Peterson, "Nervous and Mental Diseases," edition of 1889, page 156, say: "Horsley believes them to be superimposed in strata: (1) Most superficially tactile, then (2) Muscular sense; (3) Pure motor elements below."

Therefore, in the destruction of one or the other layers, we get paralysis with or without anæsthesia, or *vice versa*.

Concentrated Milk.—The *Journal of the Society of Arts* is responsible for the statement that a Gothenberg physician has invented an apparatus by which milk can be brought into the form of a powder similar in appearance to flour, and possessing all the qualities of milk in concentrated form, moisture excepted. It is maintained that the flour is perfectly soluble in water, and can be used for all the purposes for which ordinary milk is employed. It is also claimed that it does not get sour, or ferment, and, in its dry state, is not sensitive to changes of the weather.

CLINICAL REPORT ON THE USE OF ARGYROL (SILVER VITELLINE) IN DISEASES OF THE NOSE, THROAT, AND EAR.*

By M. D. LEDERMAN, M.D.
NEW YORK.
ADJUNCT PROFESSOR OF DISEASES OF THE NOSE AND THROAT, NEW YORK POLYCLINIC; ASSISTANT AURAL SURGEON, MANHATTAN EYE AND EAR HOSPITAL; CONSULTING AURIST, BEDFORD HOSPITAL, ETC.

Synthetical chemistry has added a variety of new products to the rapidly-increasing number of pharmaceutical preparations. Time does not permit the active practitioner to test the merits of each new remedy, and consequently he selects those which appeal to him, in the hope that they may demonstrate some of the advantages claimed for them by observers who have carefully noted their virtues after due clinical investigation.

During the early summer Dr. A. C. Barnes of Philadelphia called my attention to his proteid salt of silver, commercially known as "argyrol." It was believed that this compound was an ideal substitute for silver nitrate, as it contained 30 per cent. of silver, which was twice the amount found in any of the proteid silver substances yet produced. It furthermore possessed the advantage of being extremely soluble, as one ounce of it is freely and completely taken up in less than a dessertspoonful of water, while other proteid salts of the metal can only be obtained in 5 per cent. solutions. Solutions of this new salt, no matter how concentrated, do not precipitate albumin or chloride of sodium, consequently exerting no caustic effects upon mucous membranes. Strong solutions of argyrol may be applied to the membrane without causing any irritation or annoyance.

Excellent results have been obtained from its use in diseases of the eye and genitourinary tract, and as no test had been made of its efficacy in affections of the upper respiratory organs, I decided to give this remedy a continuous trial.

My observations with the use of argyrol, both in clinical and private practice, extend over a period of five months, and embrace the treatment of acute and chronic catarrhal disturbances of the nose, pharynx, and larynx, and chronic purulent disease of the middle ear. Solutions of silver nitrate were entirely discarded during this time, and the new salt was employed in strengths varying from 5 per cent. to a saturated solution, whenever the opportunity presented.

When silver nitrate is applied to the mucous membrane it promptly demonstrates a coagulating action which limits its influence to the superficial tissues and retards further penetration, so lessening the therapeutic value of the local treatment. To show how thoroughly argyrol finds its way through animal structures, Dr. Barnes, in his original report,† quotes an experiment carried out by Dr. Edward Martin. A strand of catgut was immersed over night in a one-per-cent. solution of this new remedy; on the following morning section of the gut showed that it was "impregnated through and through with silver. The integrity or flexibility of the catgut was in no way impaired by the immersion." If this penetrative power is true in structures devoid of physiological function, it certainly should prove of value in living tissue. We must not overlook the fact, however, that the application of any such solution must act promptly, especially on tissues of a secretory nature, otherwise the activity of the glandular structure will overcome part of the local effect. The astringent property of any silver salt, no doubt, assists materially in augmenting its alterative tendency, and the deeper the penetration, the greater its therapeutic value. Genitourinary surgeons have observed that this salt penetrates deeply, without causing any disturbing chemical change of the submucosa. This, no doubt, accounts for its decided bactericidal powers, with freedom from irritation. The same pleasant features were observed in diseases of the respiratory mucous membrane.

---

*Read before the Metropolitan Medical Society, October 28, 1902.

†Medical Record, May 24, 1902.

The solutions were applied in the usual manner, with a cotton-wrapped applicator. Starting at first with a 5-per-cent. solution, I rapidly increased the strength of the solutions to 20, 30, and 50 per cent., without the slightest sensation of smarting, or the unpleasant subjective experience of constriction or "dry" sensation which so frequently follows the use of silvernitrate solution.

In acute rhinitis, of the ordinary "cold in the head" variety, 10 to 30-per-cent. solutions were employed, after a preliminary treatment with a 1 to 3,000 adrenalin solution. The depletion following the use of the adrenalin was certainly prolonged by the astringent and penetrating properties of argyrol. No irritation was experienced at any time from these applications, and this feature argues well for the new product, as the nasal mucous membrane, during an acute coryza, is exceedingly sensitive to any solution. In four cases of vaso-motor periodica, repeated applications of a 20-per-cent. strength were employed with noticeable improvement in the attacks of paroxysmal sneezing and a material lessening of the hydrorrhœa. In two of these cases the treatment was carried out daily for ten days, while in other cases the treatments were made on alternate days. In these patients no annoyance was experienced from the solution, and when we recall how exquisitely sensitive the nasal mucous membrane is under such conditions, we can readily appreciate the advantages of a remedy which possesses bactericidal and antiphlogistic virtues, without increasing the existing local discomfort.

In cases of chronic catarrhal changes of the larynx, the mucous glands were promptly stimulated by the application, and the patients remarked that the parts felt quite moist and more comfortable for a few hours after its use. The disagreeable sensations which follow the local use of the nitrate of silver were not observed at any time after the treatment with argyrol. During the treatment of a physician suffering from a subacute laryngitis, the solution was rapidly increased from a 10 per cent. to a 30 per cent., without the slightest symptom of irritation or annoyance. In the same person a 1-per-cent. solution of the nitrate salt caused considerable local discomfort.

In attacks of acute pharyngitis, solutions of 30- and 50-per-cent. strength were employed daily for three treatments, with prompt relief from the dysphagia and a decided change in the engorged tissue. The same effect was noticed in acute tonsillitis and in nasopharyngitis. Two cases of mucous patches of the pharyngeal and tonsillar tissues were treated with the 50-per-cent. solution. The local soreness improved rapidly, and the lesions disappeared in a period of ten days. Of course, internal medication was given, and a gargle of lotio nigra was used, three times daily. Cases of chronic nasopharyngitis, in which "post-nasal accumulations of mucus" was the prominent symptom, were treated with 30- and 50-per-cent. solutions every other day to the rhinopharynx after the use of a cleansing spray. In these patients the mucus was more readily expelled, and the character of the secretion showed that the stimulating action of argyrol was very prompt. Instead of the usual plugs of retained secretion, the collections became more fluid in consistency and less in quantity. The same feeling of moisture was noticed by the patient as in that class of cases in which the membrane showed an atrophic tendency.

That this new product possesses distinct advantages over other salts of silver, was demonstrated to my satisfaction in a case of persistent herpes of the mouth, lips, palate, and tongue, following an attack of herpes zoster in a female about fifty years of age. The eruptions were very painful, and caused much distress, on account of the suffering during mastication and deglutition. Nitrate of silver and protargol were employed, but the stronger solutions caused so much irritation that they had to be abandoned. Argyrol was then applied in 50-per-cent. strength, with a decided amelioration of the local symptoms. In fact, at one time the eruption had entirely disappeared under its use, but reappeared, and is again improving under the same treatment.

In chronic suppurative otitis, with good-sized perforations, without excessive granulation tissue, a 50-per-cent. solution was permitted to flow into the middle ear through the opening in the drum. In one instance of long-standing disease, with repeated infection of the middle ear, from the Eustachian tube, the strongest solution was introduced into the tympanic orifice of the tube, by means of a slender cotton applicator, and carried toward the pharynx for nearly an inch without exciting any local annoyance, either objectively or subjectively. In this instance and in other cases which showed a mucopurulent discharge, without much osseous necrosis, the mucous membrane became paler and less boggy in appearance and the discharge assumed a more mucoid character. In three cases I have applied a saturated solution of this salt to the tympanic attic without causing any discomfort.

Dr. Barnes informed me that he has applied a crystal of argyrol to his own conjunctiva without causing any irritation.

My experience with this new salt of silver permits me to feel that it is a worthy substitute for the nitrate. It possesses the good qualities of our old friend without the latter's unpleasant irritating features, especially in its application to the nasal, pharyngeal, laryngeal, and aural mucous membrane. As yet I have not employed it in catarrhal manifestations of the Eustachian tube, by way of the catheter, but I am inclined to believe that it is safe to introduce weak solutions of this salt into the tube, after the nose and rhinopharynx have been satisfactorily cleansed.

Dr. Robinson of the Manhattan Eye and Ear Hospital's house staff has used a 50-per-cent. solution of argyrol in a few cases of acute purulent otitis media with pleasant results. The ear is first cleansed with an antiseptic and the "argyrol "solution is then instilled into the canal. This treatment is carried out three or four times daily. He informed me that the infectious process seemed to be retarded, and that extension to the mastoid did not occur as frequently.

Monarticular Disease.—I am convinced that single rheumatic joints never exist. If joint disease is due to rheumatism, more than one joint will become infected; every single joint disease is always purulent, tuberculous, gonorrheal, or due to pneumococcus or to some central nerve lesion.—A M Phelps

RELATION OF CONSCIOUSNESS TO THE NERVOUS SYSTEM.

By AXEL E. GIBSON, M.D.,
LOS ANGELES, CAL.

The nervous system, as it presents itself to-day, is made up by numberless polymorphous cells sending out fibers in various directions in a fashion strikingly resembling the branches of a tree. With the exception of one—the trunk or neuraxon, which proceeds directly to the tissue or function to be innervated—these branches or dendrites, terminate in the proximity of the parent cell, to form a dense network, the aggregate mass of which, including the cells themselves, constitutes the gray matter of the brain and spinal cord.

Physiologically and topographically considered, the nervous system permits of a two-fold division: the cerebrospinal and the sympathetic—each system distributed over a rather definite area of innervation. The former supervises the instinctive or psychic processes of life; the latter is related to the vegetative or vital, while, as representing states of consciousness, they are both mainly below the sphere of self-consciousness.

The cerebrospinal system has its center in various levels of the medulla and fourth ventricle, while its subordinate centers extend down the entire length of the spinal cord, from which, through the intervertebral foramina, it sends out a number of equidistant and equilateral fibers, which constitute the thirty-one pairs of spinal nerves.

With the sympathetic system, we understand that unique aggregation of fibers, plexia and ganglia, which ramify throughout the body, supplying the purely vegetative functions of life, such as the internal viscera, blood vessels, and secretory glands, in contradistinction to the cerebrospinal, which mainly innervates skeletal muscles and functions of special sensation. The sympathetic system is located in a chain of some twenty to twenty-three ganglia, strung out on both sides of the spinal column, with which they are in intimate connection through communicating spinal nerves. Besides this double central chain of ganglia, the sympathetic system possesses a number of other ganglia, located at different places in the body, of which the solar plexus and semilunar ganglia are the most important.

Normally, this sympathetic system appears to be able to carry on its functions without the necessity of cerebrospinal interference. A complete separation may be brought about between the two systems by a sectioning of the connecting spinal fibers, the rami communicantis, without any immediate break in the continuity of the sympathetic functions. Dogs have been kept alive for weeks after their entire spinal cord had been rendered inactive, and, in Pflüger's *Archiv fur die gesammte Physiologie*, a case is reported in which a child was born without a trace of cerebrospinal column. Though the child did not survive birth, the case, nevertheless, goes to prove the power of the sympathetic system to maintain vegetative functions in perfect independence of cerebrospinal interference.

Another feature of distinction between the two systems is manifested in the rhythmic movements characteristic to the functions or tissues innervated by the sympathetic system. This rhythm, which is inseparably connected with the normal functioning of the heart, lungs, intestinal viscera, etc., contrasts most markedly with the disconnected spasmodic and abrupt movements of the skeletal muscles and sense-functions, which are directly under cerebrospinal control. In a word, the sympathetic system seems to be in closer touch with the great life of nature and more receptive to its harmonious health-bearing impulses.

Yet these differences between the two systems, however striking they may appear, are more apparent than real. The study of embryology has revealed facts which lead to the conclusion that the sympathetic system is an outgrowth of the cerebrospinal. The development of the fœtus presents in a series of quick, consecutive steps, corresponding stages of evolutionary growth once passed through. The science of embryology enables us to trace back, step by step, the adventures of the human creature during its sojourn in a dim, biological past. The invertebrate stage is followed by the vertebrate; the imperfect notochord is developed into the magnificent spinal column, with its elaborate network of nerves and ganglia. And as the evolutionary impulse, with resistless energy, continues to force its products to ever higher levels of attainment, followed by a corresponding increase in functional complexity, a more systematic division of labor is needed. The cerebrospinal system, ever harder pressed for service in its life-and-death struggles with stern environment, yields to the necessity of establishing specialized centers of innervation. In response to the waves of sensory impulse, which a constantly increasing complexity of function sends to the spinal column, a chain of ganglia is formed around the latter. Thus, in the course of time, the purely vegetative functions are provided with reflex-centers, or nervous storage-batteries, through which the routine of nutrition and secretion is governed; and the sympathetic system, with all its intricate mechanism of plexi and ganglia, is thus brought into full operation.

From this point of view, the solution to the problem of a fœtus existing without the aid of a cerebrospinal system is logically found. The intimate physiological relation existing between the fœtus and the mother would make it scientifically possible for the cerebrospinal system of the latter to substitute the missing one in the fœtus.

The sympathetic system is practically a series of relay-stations, in which the cerebrospinal system is storing up nervous energy for further distribution to the vegetative functions in course of demand. For the discharges and distribution of the sympathetic ganglia take place in response to stimuli reaching the system through the elaborate functional leverage of demand and supply at work in the bodily metabolism. Waves of protoplasmic energy, set free in the system through the assimilation and absorption of food-stuffs, sweep through the sympathetic area in unceasing rhythm. The cyclic movement of the heart, the periodic motion of intestinal peristalsis, the singular rhythmic action demonstrated in spleen, liver, kidney, and other secretory glands—functions which all are more or less under sympathetic control—manifest this rhythmic influx and efflux as forming a substratum for all vegetative existence.

Through this rhythmic movement the sympathetic system is related to cosmic evolution. For rhythm is universal. We encounter the rhythmic order in the movements of the stars and planets, suns and moons; in the seasons of the year; in the oceanic tides; in the recurrence of days and nights; wake and sleep; life and death. In rhythm lies the very basis for organic existence—the agency for cosmic order. The closer we approach the heart of nature and live in accordance with her demands, the more vigorously shall we feel the strengthening touch of her rhythmic impulses.

Hence, we are entitled to regard the presence of rhythm in the sympathetic system, and its non-presence in the cerebrospinal, as due to the isolation of the former from the disturbing impulses generated in the play of fear, imagination, and desires, which are constantly influencing the workings of the cerebrospinal consciousness. Left to the care of its own nature, the sympathetic system performs its functions under guarantees of enduring health and strength. But, owing to the fundamental identity underlying the two systems, a disorder in the one is sooner or later reflected into the other, and the health and vigor original with the sympathetic system must gradually succumb to the abnormal impulses reaching it from a disturbed cerebrospinal center. And as cause and effect are inseparably bound up in the same cycle of events, the cerebrospinal center from which a disturbance may have come must restore the disturbed order by generating harmonizing and compensating impulses.

Considered *per se*, the nervous system of man differs neither in a functional nor structural way from the nervous system of the animal. The operations of either system are based on purely mechanical principles. Thus the valve of the pylorus is flung open to permit the passage of the peptonized food the moment the latter, through the process of gastric digestion, is rendered fit for intestinal digestion and subsequent absorption. Behind this startling phenomenon of the pyloric sphincter muscle, which, while hermetically closed during gastric digestion, is spontaneously opened for the food when the latter is properly prepared, lies the principle of mechanical leverage. The closing of the valve is due to the constrictive influence of the sphincter nerve, which asserts itself as long as the presence in the stomach of undigested food serves as an irritant to contraction. Reduced to a soft, pulpy mass, the food ceases to irritate, and the sphincter muscle, yielding to its natural tendency to relax, leaves passage for a discharge of the gastric contents. The circumstance that even indigestible material, like seeds of berries, cellulose, and poorly masticated food are ultimately permitted passage to the small intestine, in spite of their undiminished power to irritate, merely refers to the physiological fact that the overstimulation of a nerve always results in its temporary paralysis.

The function in which the mechanical principle is brought to its highest and most wondrous perfection is found in the heart. The point of unstable equilibrium maintained between the rate of muscular expenditure in any part of the body and a compensatory rate of heart-beat on the other, exhibits wonders of accuracy in the functional leverages involved. Thus the increased expenditure of muscle tissue caused, let us say, by fast walking, is instantly responded to by an increased action of the heart, through which a greater blood supply is furnished for the repair of the broken-down tissue. The demand by the muscles for more blood has been answered, and the state of unstable equilibrium is thus maintained.

The principle of mechanical leverage involved in this phenomenon may be traced thus: the fast walking results in an increase of catabolic changes in the involved muscle-substance, at a rate preventing the normal elimination of the ensuing waste-products. The accumulation of these products introduces mechanical and chemical changes in the nerves ending in or passing through the deranged area, and which respond by at once sending an irritation to the medulla *via* spinal cord. In consequence the medulla coordinates the sensory impulses into a vasomotor impulse, which proceeds along the motor fibers to the seat of irritation, and there, by dilating the caliber of the blood vessels, allows the passage of a larger blood stream. The force of blood-pressure in the circulation, following the dilatation of blood vessels, removes the check of resistance which a high-blood pressure always exerts on the movement of the heart. The latter, being thus momentarily set free, increases its action, resulting in a larger volume of blood flowing into the deranged tissues, and thereby quickening the elimination of the waste products, and, as a natural consequence, bringing about the restoration of normal equilibrium.

Again, the increased rate of oxidation which attends the downbreak of tissue is always accompanied by an increase of heat. Having reached a certain degree, a further increase of heat would endanger the safety of functional activity, and must therefore speedily be eliminated from the body—a process involving the introduction of a new set of mechanical changes. As we have nerves that register qualities of softness, hardness, and weight, so we likewise are provided with nerves registering qualities of heat and cold. Now, when the temperature of the body,. or in a given part of the body, rises above the normal,these nerves become irritated. The irritation of a nerve means the temporary introduction of a change in its constitutional arrangement, and as it proceeds to the central office—the medulla—the character of the response to be initiated must, of necessity, depend on the character of the cause of irritation. If, as in this case, the irritation be caused by heat, the response will be manifested in a reflex irritation from the medulla, conducted on sympathetic motor nerves, which start the operation of a sweat vasomotor mechanism, based on similar principles as the one operating on the blood vessels. The influence of these sweat nerves will dilate the sweat capillaries with which they are connected, thereby permitting the osmotic pressure of the blood stream to cause the flow of perspiration through the pores of the skin. This means the immediate fall of bodily temperature, as the evaporation of sweat, by which is to be understood the process of splitting the sweat-molecule into its atomic constituents, requires a large absorption of heat. A similar ingenious system of levers, based on the mechanic principle, can be traced in the operation of every functional activity of the body.

The phenomena of high pressure, as manifested in the blood, lymph, and sweat, is ultimately due to the presence of a living, dynamic energy in the protoplasmic substratum which supports every manifestation of life. This exhaustless fountain of power, ever ready to burst forth when conditions permit, is regulated and controlled by the coordinating, synthesizing activity of the nervous system. Hence, the ever-present tendency of normal metabolism to accelerate the action of any function as soon as its restraining checks, administered by the controlling nerve, are removed or weakened. Thus the inhibition of the vagus nerve, which acts as a check on the movement of the heart, sets free the latter to follow the protoplasmic impulse resulting in wild, ungoverned beatings. Glandular activity is governed by the same principle. A loosening of the checks by which the vasomotor mechanism governs the glandular functionings results in a virtual bursting forth of the respective secretive fluids.

From this it follows that the maintenance of functional activity involves, primarily, the presence of two factors: the protoplasmic storage batteries of vital force on the one hand, and an elaborate system of conductors on the other; while the successful co-operation of these two factors depends on the perfect workings of a mechanical, inter-structural leverage.

The nervous system holds the bodily tissues in a state of constant tension, and the equilateral distribution of the cerebrospinal nerves renders it possible, in normal cases, for this tension to yield a perfect structural equilibrium. In fact, the facility of muscular movement is due to this steady pull, uniformly exerted on all parts of the structural tissue and permitting them to move as if balanced on a frictionless pivot. So accurate is the poise of this general tension that its presence is perfectly unsuspected, until abnormally interfered with. But the paralysis of, let us say, a facial nerve reveals at once, with appalling severity, the hidden mechanism. A distortion of muscles takes place on the opposite side of the median line, as a result of the failure of the paralyzed nerve to equalize the tension which the corresponding healthy nerve exerts on its muscles. Hence the distortion of a muscle does not indicate the real seat of the disorder.

In the mechanism of the heart we find the same principle at work. The heart trembles in the balance between the ever-fluctuating pull exerted by its pair of opposing nerves—the accellerator, tending to loose the heart strings; the inhibitor, to tighten them. The result is the maintenance of an unstable equilibrium in the cardiac cycles.

The phenomenon, or, perhaps, better expressed, the noumenon, of life which gives to human existence its crowning perfection and transcending purpose, lies in the rise of self-consciousness. While in the animals, and, as some naturalists assert, even in the plants, we find the manifestation of an instinctive consciousness, it is first, however, in the human being that consciousness *per se*, by being rendered capable of exerting the power of self-analysis, is raised to the level of self-consciousness. And even granting to some men of science the accuracy of their statement, that no analysis, however keen and painstaking, can trace in the field of evolution the dividing line where consciousness is turned into self-consciousness and instinct into reason, the concession must nevertheless be made that it is first in man this phenomenal widening of the area of consciousness has become a telling factor in the evolutionary process.

The evolution of self-consciousness, as manifested in the human being is, *sui generis*, and not demonstrable as a product of functional or structural operation. And while the student of embryology has no difficulty in demonstrating the sympathetic system to be an outgrowth of the cerebrospinal, no amount of application to that field of study has so far succeeded in exploring the obscure subject of self-consciousness—its genesis and purpose. The failure of any aspect of physical evolution to solve the problem of self-consciousness lies in the circumstance that the latter seems to be superimposed upon the whole biological output, manifesting in the evolutionary processes, not as effect, but as selective, determining cause. From this it follows that a pursuit of the study of self-consciousness, if it is to be scientifically gauged, must be directed, not toward the past, but toward the future.

The cerebrospinal system, while controlling the sympathetic, is itself operating under the cover of instinctive consciousness and below the reach of individual self-consciousness. The medulla, through its vasomotor mechanism, may administer a checking influence on a hyperæmic tendency of the liver, without a single step of the elaborate process being revealed to self-consciousness. Man, as thinker and reasoner, is a perfect stranger to man as animal or plant. Of his vegetative self he knows only from reports based on more or less successful scientific theorizing. Unable to intelligently identify himself with the sustaining functions of his own being, he depends for his self-knowledge on the power of his imperfect senses to lay bare for him the incidents of the problem. And as the senses, as outgrowths of the vegetative life-process, are themselves a part of the problem, it does not appear likely that through sensation alone we shall ever be able to master the task of self-discovery.

While the paths travelled by sensation are scientifically demonstrable by means of sectioning and isolation of the corresponding nerve-threads, the paths occupied by the movements of self-consciousness remain absolutely trackless—a fact, however, which does not diminish the immense influence which this unique force exerts on man's involuntary career.

The incentive to growth, which the power of self-analysis may impart to the individual, overbalances, by far, every other factor in evolution. The reactions brought to bear on the human being, through the storm of inner and outer impulses assailing his mind, are, by virtue of this silent, invisible, impapable factor, rendered apprehensible and turned into potent elements of mental, moral, and physical growth. Through self-consciousness evolution has received a new source of power. Existence, from being monopolar, has become bipolar. At the one pole the protoplasmic life current, with convulsive energy, pours forth ever new impulses of growth and power into evolution, while at the other self-consciousness adjusts the vital reactions into new combinations of available energy. Below, life; above, light; below, the basis of evolutionary structure, with its Titan masonry of potential, unorganized, world-moving power; above, the towering of a constructing, fashioning, completing architecture. Under the guiding light of self-consciousness, the simple movements of the single cell are transformed into the complex movements of the collective cell. The amœba has expanded into a being of thought and reason; the promise faintly advanced in the mystic movements of mitosis has, in the powers of the human being, received its dazzling fulfilment.

Still the object of life is as yet only partly won. Through the evolution of self-consciousness new fields are opened for evolutionary advances. Self-consciousness is at once both end and means, agency and agent, and its progress must be found along the lines of efforts through which the power of self-conscious identification may be extended to every function of the bodily mechanism. Man is advancing toward a stage of evolution when he shall no longer remain a stranger to life-processes at work in his own being. Perfection of the human creature does not consist in being subject to sensations, but in the subjection of them.

At present the average human being, with all his accomplishments, stands a captive in the midst of a surge of emotions and sensations, over which he is unable to assert self-mastery. Feelings and sentiments fly along invisible and undefinable highways of consciousness, and spring into life and power often as much of a surprise to the subject himself as to those who observe him. Impulses born from emotions of "airy nothings," and moving along trackless pathways, are still capable of initiating structural and functional changes in secretory and circulatory tissue. What physiologist can trace the

Ariadne thread of an emotion from where it emerges, in the "psychic centers" in cortex, to its destination in the secretory mechanism of the lacrymal gland, to manifest in tears? The moods of the mind may be clearly definable in the ebb and flow of purple waves moving across a person's face, yet the stimulating forces which, while in themselves substanceless and impalpable, are still potent enough to bring into operation the leverage of a well-defined blood-regulating, vasomotor mechanism, involves an agency which as yet defies the scalpel and microscope of science. The individual has in his charge a mechanism, over which, to a large extent, he has no control. As a child, carelessly passing through some modern exhibition of mechanical wonders, may introduce startling phenomena by the mere turning of a crank or pressing of a button, so man, as he passes through his span of life, is carelessly playing with his passions and emotions unconscious of the scope and purpose of the forces he is thus liberating.

The genius of evolution is not exhausted in the master efforts wrought in physical forms and structures. Were such the case, man would not find himself advanced beyond the sphere of the animal. In some aspects he would even occupy a position below it. In matters of circulation, secretion, innervation, structural integrity, division of functional labor, general metabolism, etc., the animal is on a perfect level with man. The basis for vegetative life, as represented in the smooth non-striated spindle-shaped, "involuntary" muscle-cell, 40 to 200 mm. long and $\frac{1}{12}$ as wide, which receives the innervation of the sympathetic nerve, has a common significance to man and animal. And, in equal degree, man and animal share the physiological advantage of a striated, highly differentiated, polynuclear, 12 centimeters long and $\frac{1}{1000}$ part as wide "voluntary" muscle-cell, which receives the cerebrospinal innervation and represents the structural basis of instinctive life. It is first in the cranial structures, in the region of cerebral cortex—the functions of which are wholly unknown—that the anatomical distinctions between the animal and man arise. And as these distinctions are principally manifested in the power of self-consciousness, it would be a matter of mere logical deduction, from given facts, to associate self-consciousness in man with an advanced evolution of the unique, non-demonstrable functions of his cortex. If this be so, then man's position as an exponent of self-consciousness receives a biological basis. On the sympathetic system he depends for his vegetative existence; on the cerebrospinal for his instinctive or psychic; while these unexplored regions of the cerebral cortex may form the structural basis for his self-conscious existence.

From this vantage ground the mind of man may be destined to extend its domain of self-consciousness to the strongholds of a powerful sensation. The work of conquest is certainly progressing, slowly but surely. Trackless connections, demonstrable only through their effects, are being established between self-consciousness and physiological centers. The calculated effects which volitional efforts may exert over emotions and sensations are *prima facie* evidences for the view that the forces of individual self-conquest are at present in actual operation.

The crowning glory of human evolution must be found in the attainment of that power through which man may become a master of himself. From being a slave of the moods and fits of a sportive, emotional nature, this power shall make of him the supreme ruler of his existence. And unselfishness of motive, steadfastness of purpose and purity of life are the mighty agents which, infallibly, will lead to the evolutionary goal: Man's conquest of himself.

A New Form of Treatment in Banti's Disease.—Benedetto Schiassi of Bologna reports a case treated in the Ospedale Umberto e Margherita in Budrio, in which the cirrhosis was so far advanced that the splenectomy advised by Banti under such conditions was not considered advisable. The ascites was first relieved by paracentesis, and a little later the operation of grafting the omentum between the muscles and the peritoneum was performed. The wound healed rapidly, but the ascites reappearing, a second intervention was found necessary. The author made a vertical incision, beginning at the border of the ribs, and extending 24 cm. downward. The spleen was found to be greatly enlarged. By methods which are described in detail the author fastened the spleen to the parietal peritoneum with the object of causing new vascular anastomoses. The patient made a good recovery. Some ascites formed, was removed by paracentesis, and has not since returned. Three months later the spleen was found by palpation to be much reduced in size. Hepatic extract was then administered daily, and in three months more the patient's general condition was in every way improved. The author gives his reasons for the treatment, the purpose of which was to increase the powers of compensation and decrease injurious influences. The first organ to be benefited was the liver, as the deviation of the portal blood so affected the hepatic circulation as to nourish the cells of that organ, the uninjured cells responding with hyperactivity. As to the administration of hepatic extract, it was given with the idea of further stimulating the liver cells, and resulted in increased diuresis and excretion of urea. Fresh red bone marrow was also given to stimulate hæmatopoiesis and restore the blood to a normal condition.

The Nicotine Question in Smoking.—Prof. Strauch says that by analysis with the Habermann apparatus, the number of substances which give strength to a cigar will be found to be much lessened. Carbonic acid and nicotine and the minute quantity of sulphureted hydrogen may be left out of consideration. There remains the group of pyridine-like bodies, among which, of course, there may still occur some violent poisons—prussic acid, for example—and finally there is the carbon monoxide. Indeed, it is extremely improbable that any single substance is accountable for the strength of a cigar; most probably a great many contribute toward it whose respective quantities will vary with each cigar, depending, however, on the form of the cigar, the amount of moisture, the rate of smoking, and many other factors. Owing to these considerations, a clear decision of the question is very remote. For the present we must be satisfied with the knowledge that nicotine has not, by far, the dangerous signification which is commonly attributed to it.—*Medical Press and Circular.*

Diagnosis and Treatment of Gastric Ulcer.—Dr. Ewald has been impressed by the large number of cases of gastric ulcer not presenting any hyperacidity. He has observed hyperacidity in only 56.8 per cent. of the cases. Hæmatemesis was present in 203 out of 304 cases, but this accident may be due to other causes. Pain is not typical, loss of flesh and cachexia are comparatively rare. The tongue is usually red and moist, only slightly or not at all furred The anatomical diagnosis of gastric ulcer can be arrived at by the course of the affection. We must ascertain whether the ulceration is primary, or whether it has been developed in the course of another affection; but in such cases the ulcer remains latent and is not of great clinical interest.—*Medical Press and Circular.*

Clinical Department.

A CASE OF MULTILOCULAR DOUBLE OVARIAN CYST, COMPLICATED WITH CARCINOMA OF THE DESCENDING COLON; OPERATION; RECOVERY.*

By J. B. BOUCHER, M.D.
HARTFORD, CONN.
SURGEON TO ST. FRANCIS' HOSPITAL.

Miss M——, aged twenty-three, single; mother died aged thirty-three, with typhoid fever; father living. Her history is as follows: Early in March, this year, she consulted me at my office, and then stated that for about eight or nine months she had had considerable pain in the left lumbar region. The bowels were constipated, requiring laxatives. The movements were frequently followed by fleshy shreds from two to four inches in length, and defecation was frequently accompanied with pain. Her menstrual periods had been quite regular until within two months. Her appetite and general appearance were good, and she continued to follow her occupation as a domestic. Examination revealed considerable pain over the lower region of the abdomen. It was somewhat tender, particularly in the left side and above the region of the ovary. A tumor could be outlined, about the size and shape of a six-months' pregnant uterus. I put her on tonic treatment and tried to regulate her bowels. She continued to see me occasionally for about six weeks, during which time I could notice some growth of the tumor, but not very rapid.

On April 25 I was called to her home. I there found her with a temperature of 104°, pulse 120, obstinate vomiting and retching; the abdomen was distended and extremely painful, and large as a full-term pregnancy. I used stomach sedatives, calomel, high enemas, etc., and after thirty-six hours succeeded in evacuating the bowels, when the patient experienced considerable relief. She remained fairly comfortable for two days, when she was again taken with more violent symptoms than before, and evidence of general peritonitis. After two days' treatment I was unsuccessful in moving the bowels or allaying the symptoms or vomiting. As her condition was becoming alarming, I advised immediate laparotomy, having made the probable diagnosis of a twisted pedicle of an ovarian cyst, or a general peritonitis.

The patient was placed in St. Francis Hospital, and, after the usual preparation, was operated on on April 30. A median incision about four inches long was made below the umbilicus. When the peritoneum was reached it was found dark and congested. On opening it we found the omentum dark, inflamed, and adherent to the anterior abdominal wall on the left side. Considerable hemorrhage was caused by separating it. The abdomen and pelvis were filled with a large multilocular cyst, composed of a great number of smaller cysts. These were emptied, and the sac and right tube were removed in mass. The left ovary had degenerated, and contained a tumor about the size of a baseball, filled with clear fluid; this, together with the left tube, was removed, and the peritoneum was stitched over the stump. The omentum was retracted, thickened, and nodular. We removed of this one nodule as large as a walnut.

After sponging out the abdomen and preparing to close it, my attention was attracted by a hard mass in the left side about the size of a hen's egg. Examination revealed a cancerous mass encircling the descending colon a few inches above the sigmoid flexure. There were several enlarged glands in that portion of the mesentery, one as large as a small marble. The mass was hard, dense, and fibrous, and contracted in the center, so that the lumen of the bowel was nearly occluded.

We decided to remove the mass, so severed the bowel above and below the growth, removing about four inches of gut, together with a V-shaped piece of mesentery, including the enlarged glands. The two cut ends of bowel were then united end to end by a double Lembert suture of silk; the silk ligature was first used to unite the mesentery, then carried around the gut and tied with the mesenteric end. The abdomen was then closed without drainage, and primary union was secured. Thirty-six hours after the operation the patient's bowels moved freely twice, but did not injure the stitches, and the patient made a rapid and uninterrupted recovery.

In four weeks she left the hospital, and has since continued to gain in strength and flesh. Over four and one-half months have now elapsed since the operation, and she has apparently gained ten to fifteen pounds; her general health is good; she has no pain, appetite is good, bowels regular, and in every way she is feeling very comfortable.

A microscopical examination of specimen was made by Dr. A. J. Wolff, and pronounced carcinoma.

An interesting point in this case was the history of two severe attacks, now looked upon as intestinal obstruction. This was, undoubtedly, the principal cause of her trouble, but its existence was never suspected until it was found at the time of operation.

Another interesting point arises: Was the cystic degeneration of both ovaries primarily or secondarily cancer? If not, what produced the shrunken, nodular omentum, with the firm adhesions between it and the anterior abdominal wall?

This case illustrates the advisability and necessity of thorough examination of all the abdominal organs during abdominal exploration. Had we been contented after removing the apparent source of trouble, we might have overlooked the cancer of the bowel, and consequently our patient would have derived but little benefit.

An interesting fact is demonstrated by this case; namely, that we can do several operations at one time, provided we are careful in sustaining the patient by proper stimulation, saline infusion, keeping close watch of temperature, and avoiding undue exposure of important structures. The secret of success in operations on intestinal cancer lies in early diagnosis; therefore the general practitioner is the one who decides the future of a case. I believe cancer of the bowels is a curable disease in a fair percentage of cases if the operation is thoroughly performed at an early date; and even at an advanced period, when we have symptoms of obstruction, we should operate and give the patient relief and prolong life, which it is possible to do in many cases. Many will recall a case of cancer of the cæcum I presented to the society last spring, after removing the entire cæcum, appendix, and greater part of ascending colon. Over seven months have elapsed and this man is still in good health and working daily.

In conclusion, permit me to say that when there are symptoms of intestinal cancer—namely, a granual loss of flesh, obstinate constipation, local tenderness, and periodical attacks of pain, unrelieved in four to six weeks of intelligent treatment—I believe an exploratory incision is not only justifiable, but our patient's best interests demand it.

ARTERIAL TENSION.

THE rapid increase in the number of instruments of precision, together with the perfection of laboratory methods, has caused a comparative neglect of the study of symptoms which were formerly all important. That this is so is a cause of regret, since both have a place in the practice of medicine, and it is our duty to study the living man as well as to analyze his secretions, or have a record of his temperature.

There can be no doubt that the study of the pulse has, to a great extent, been neglected; many observers being content with merely noting the force, frequency, and regularity, and paying but little attention to other characteristics.

One of the most important clinical points in the treatment of circulatory and renal diseases is to be found in the degree of arterial tension, a condition not readily recognized by the novice, to be sure, but to one who has studied this characteristic faithfully it becomes readily detected even in its more delicate shades.

Only too often is the laboring heart so exhausted by its endeavors to overcome the arterial resistance that it gives the clinician the impression that a stimulant is indicated, and consequently insult is added to injury, and the heart is whipped to work harder instead of having its load lightened. Digitalis often fails to give relief, simply because we forget that it causes the arteries to contract strongly. This property of the drug is a valuable one when the tension is low, and it has honestly earned its reputation as the best drug at our command in the usual cases of chronic valvular disease with failing compensation. It is quite otherwise, however, in those cases of arteriosclerosis, plumbism, gout, and chronic diffuse nephritis in which the tension is high and in which it becomes our duty to lessen the work for the heart to do, and by resting it, strengthen it. Many asthmatic attacks, headaches, attacks of convulsions, muscular twitchings, vomiting, prolonged epistaxis, apoplexies, angina pectoris, etc., can be traced to this cause, and may be relieved or prevented by means which lessen arterial pressure. In very urgent cases, amyl nitrite, chloroform, active purging, and even venesection, become most valued methods of treatment. Chloral, so justly considered a cardiac depressant, may, in small doses, serve our purposes well, simply because it lessens the work for the heart to do by lowering the pressure through its dilating effect on the arteries. Thus a depressant becomes a cardiac strengthener by allowing that organ comparative rest. Nitroglycerin is another valuable agent, and has gained most of its reputation as a cardiac stimulant simply because it opens the arteries. For those cases of less acute character in which the arterial tension remains steadily high, or comes in attacks, much can be done by regulating the mode of life, simplifying the diet, avoiding fatigue and undue exposure and looking after the eliminations. Of drugs, iodide of potash seems to be the most reliable and should be given for long periods.

James Mackenzie, in his recent book on the "Study of the Pulse," thus decribes the pulse of high arterial tension: "The impact of the oncoming wave may be somewhat gradual in attaining its maximum force, and sometimes the tracing obtained presents a sloping upstroke, or may even be anacrotic. If the heart be strong and contracting vigorously, the pulse wave may strike abruptly, as in certain cases of Bright's disease, or in slow pulse with fever, in which the arterioles have not relaxed. After attaining its maximum force the pressure does not fall suddenly away during the diastolic period. In this particular the pulse of increased arterial pressure under discussion differs from that in which there is great increase in the arterial pressure during systole, and a great fall in pressure during diastole, as occurs most typically in aortic regurgitation, and in large otheromatous arteries during febrile excitation of the heart. In the pulse of continuous high pressure the dicrotic wave is not perceptible to the finger as a distinct wave, but is merged in the resistance offered to the compressing finger. The aortic notch is high above the level to which the tracing falls at the end of the diastole—in striking contrast to what occurs in aortic regurgitation. The shock of the oncoming wave in the arteries may be felt by the patient over his whole body when the heart is acting with great vigor. Although the pulse rate may become slower with increase of pressure, it is far from being the rule that a high pressure pulse is a slow pulse. In many cases the pulse rate may continually be ninety and over, with chronic Bright's disease, and yet the pulse retain its peculiar cord-like quality. In cases of recurrent high arterial pressure the pulse rate generally becomes slower."

No instrument has yet been invented which tells us so truly the degree of tension within the arteries as do the trained fingers of the experienced observer, and it behooves us not to be discouraged if at first we are unable to detect the less obvious changes from the normal, but merely by constant comparison gradually establish a standard which we should consider a healthy one, to recognize its normal variations and eventually to know what degree may be considered pathological.

REPORT OF THE SURGEON-GENERAL OF THE UNITED STATES ARMY.

THIS annual report for the fiscal year ending June 30, 1902, has been issued recently. The rates of admission to sick report for disease and injury, the rate of discharge for disability, and the mortality rate for the calendar year 1901 all agree in being considerably less than the corresponding rates of the year 1900. The admissions to sick report in 1901 constituted 1,791.59 per thousand of strength, as compared with 2,311.81 in 1900 and with 1,502.47, the mean annual rate of the previous ten years.

The rate of discharge for disability was 19.95 in 1901, as compared with 22.60 in 1900 and with 16.69 for the decade, and the death rate from all causes was 13.94 per thousand men, as compared with 22.74 and 11.91 respectively. Deaths from disease constituted 9.58 per thousand of mean strength, as compared with 15.79 in 1900 and with 8.49 during the years of the decade, and deaths from injury 4.36, as compared respectively with 6.95 and 3.42. During the year the mean strength of the army consisted of 92,491 men, of whom 81,885 were regulars and 10,606 volunteers.

The admission rate for troops serving in Porto Rico was 1,367.74 per thousand of strength, in the United States 1,550.25, in Cuba 1,557.49, and in the Pacific islands and China, 1,928.14. The death rate from all causes was 5.29 per thousand of strength in Cuba, 6.90 in the United States, 7.81 in Porto Rico, and 17.96 in the Pacific islands and China. Deaths from disease constituted only 3.21 per thousand in Cuba, 4.68 in the United States, and 12.40 in the Pacific islands and China. The mean strength of the commands were: In Porto Rico, 1,153; in Cuba, 5,297; in the United States, 26,515, and in the Pacific islands and China, 59,526.

Referring to clothing, the report says: "For field uniform the present campaign hat is the most satisfactory headgear yet devised. The lightweight flannel shirt is also excellent, but should be made of Khaki color, both as leading to decreased visibility, and because the lighter color would be cooler. High shoes, of the hunting type, are recommended for use in tropical climates, as they prevent infection by dhobie itch.

With regard to the most suitable ration for tropical climates, the report says: "Continued experience tends to disprove belief in the advantages to be derived from a reduced ration lessened in the amount of nitrogen and fats. In the theoretical discussion of this subject claims are made that, as the food in the tropics is not required for the maintenance of bodily heat, it might, with advantage, be reduced, especially in those foods which are heat-producing. Other theorists have gone even further, even to the point of contending that, rice being the staple food of natives, should be adopted to the exclusion of all else by the white man dwelling in the tropics. Heat-production must go on in tropical countries as in temperate climates; in fact, a certain amount of heat-production is essential as long as life lasts. The balance is maintained not by decrease in food, but by increasing heat loss by the use of lighter-weight clothing.

The main factor on which the amount of food needed depends is work. That a soldier's work in the tropics is less than in a temperate climate is not true. The results accomplished may be less, but tissue is used up with much more rapidity in a mean temperature of 85° F. than at 50° F., and an ample supply of good food is required to make good this waste, the effects of deprivation being shown immediately in reduced strength and health.

The most prevalent disease among the United States troops during the calendar year 1901 was malaria, but the death rate from it was exceedingly small. The most deadly malady was tuberculosis. Four hundred and fifty-two cases were reported from the army in the course of the year, equivalent to an admission rate of 4.89 per thousand, the death rate being 1.03 per thousand. Five hundred and ninety-four cases of typhoid fever were reported during the year, with seventy-eight deaths. In the army, as a whole, 125 cases of smallpox were reported, thirty-seven of which proved fatal, all these latter occurring in the Philippines. A large number of cases of measles were reported for the calendar year 1901, while scarlet fever was infrequent. Dengue was very prevalent among American troops in the Philippines, giving 31.67 cases per thousand of strength in the division there. But fourteen cases of yellow fever occurred in the army throughout the year. Since the early part of the current year cholera has attacked a limited number of American soldiers, and there have been some deaths. Alcoholism has kept at much the same ratio among the soldiers of the United States during the past year as in the years immediately preceding. One hundred and sixty-six cases of insanity were reported for 1901. An insignificant number of soldiers suffered from bubonic plague in the Philippines in the early part of the fiscal year, but the disease seems to have disappeared from among the civil, as well as the military, population at present. Two hundred and seven cases of heat stroke were reported, equivalent to 2.24 per thousand.

During the calendar year 1901 there were entered on the reports of sick and wounded of the army, mean strength 92,491, 17,736 cases, or 191.77 per thousand of strength, with 407 men discharged for disability and 403 having a fatal termination, equivalent, respectively, to 4.40 and 4.36 per thousand of strength.

When the fact is taken into consideration that by far the larger part of the United States army was serving in the Philippines at the time the report covers, in a climate unhealthy to white men, and under conditions incidental to the style of warfare pursued there, it must be admitted that the health of the army for the calendar year 1901 has been quite as satisfactory as could have been anticipated.

TREATMENT OF THE WOUNDED IN NAVAL ACTIONS.

This matter is one that is engrossing the attention of most earnest medical naval officers at the present time. It is felt by them that adequate arrangements have not been made, in many of the navies of the world, for the treatment of the injured, either in peace or in war. The treatment of the wounded, under the existing conditions of naval warfare, may be said to be an almost unknown quantity. There have been no battles at sea within the past thirty years—with the exception of the Japan-China and the Spanish-American wars—calculated to give a clear idea as to what would happen in modern naval warfare, and how the wounded would fare. Both the Japan-China and Spanish-American naval battles were so one-sided that the lessons learned from them were of little use. The Chinese gave no medical report of their engagements, neither did the Spanish, and the Americans did not suffer sufficient casualties to make their narration of any practical value. There remains, then, only the report of the Japanese naval medical service, which, while excellent, is too limited in its scope to serve as a guiding light.

At the section on naval and military medical matters, at the last meeting of the British Medical Association, Fleet Surgeon Gilbert Kirker read a paper in which he dealt with this subject at some length. Surgeon Kirker is the inventor of an "ambulance sleigh" for transporting the wounded easily and expeditiously to whatever part of the ship the operating room may be in, and which was referred to in the MEDICAL RECORD of September 21, 1901. Surgeon Kirker, in the paper read by him this year, said, with regard to the surgeon's station during an engagement at sea:

"In most navies there is no position specially designed for them. In each ship the captain and medical officer select what they consider the most suitable locality. . . . To deal at all satisfactorily with the wounded, the surgeon's station should consist of two parts, namely, a place where the wounded could be gathered together, or a 'collecting station,' and a place where surgical operations could be performed. For the first, some protected and sufficiently commodious part of the ship could be selected and the necessary arrangements improvised. On battleships and first-class cruisers there is ample accommodation on the middle and lower decks respectively for this. On these decks there would be few men stationed during action.

"In my former paper I suggested that certain ships should be fitted with an operating room, which could be used both in peace and war. This suggested operating room should be included in the internal arrangements of every modern battleship and cruiser. It need not be large, but it should be fitted up to meet the requirements of asceptic surgery. Neither need it be particularly easy of access, for with the 'ambulance sleigh' injured men can be easily and safely taken down and along all ordinary hatchways and passages. During peace, important surgical operations will be done in it, instead of in the overcrowded sick bay, and in it, also, the valuable surgical instruments would be kept in readiness for use. In time of war the surgeons' surgical instruments and dressings would be protected in this place during action, and after action surgical operations could be done in it with more chance of success than in the constantly-used bathrooms or greasy mess places."

The innovation recommended by Fleet Surgeon Kirker seems, at least to the non-naval man, one that with advantage might be promptly adopted. Doubtless officers of the navy, outside the medical service, will detect in the proposed plan many objections. They will say that the space is wanted for some purpose directly connected with fighting, and that everything must be subordinated to the exigencies of the situation. Others may contend that hospital ships will be present in ample numbers to take on board the injured, and to treat them in the best possible manner. For reasons too numerous to state here, it is by no means certain that the hospital ships will always, or even often, be where they are needed. In the cause of humanity, then, there assuredly should be some portion of a man-of-war set apart as an operating room, although such a course may interfere to a slight extent with the fighting powers of the ship. The most telling argument in favor of this recommendation is the fact that both the German and Japanese navies have operating rooms on board their battleships and large cruisers.

ALCOHOLISM AND INSANITY

The relation of alcoholism to insanity has been freely discussed among medical men almost from time immemorial. The fact has always been admitted that excessive indulgence in strong drinks is a factor in the production of mental aberration. The point of the argument has been as to what extent inebriety is the cause of insanity. Some have held and some still hold that alcoholism as a factor in the causation of brain affections has been and is much exaggerated. On the whole, however, alienists of the present time recognize that drinking is one of the chief means of rendering individuals irresponsible for their actions, and of peopling the lunatic asylums to the degree which now prevails.

Dr. Robert Jones, Superintendent of the London County Asylum, Claybury, writes in the *Lancet*, October 25, on the subject, and says in part: "There are probably at the present time no less than 110,000 certified insane persons in England and Wales alone, of whom, approximately, about 50,000 are males and 60,000 are females. If the Lunacy Commissioners' Blue Book for England and Wales be consulted the proportion per cent. of instances in which alcohol has been assigned as the cause of insanity to the yearly average number admitted into asylums in the five years 1895–1899, inclusive, is 21.8 for males and 9.5 for females. The proportion is much higher in Scotland, and, after allowing for the deaths of those whose form of insanity is more immediately fatal than those caused by alcohol, there are, I believe, upon the lowest computation, remaining in the asylums at the present time no less than 10,900 males and 5,800 females who are mentally decrepit through the effects of alcohol. During the time that the London County Council's asylum at Claybury has been opened, from 1893 to the end of 1901—a period of less than nine years—8,493 patients (3,776 males and 4,717 females) have been admitted thereto, of whom 21.2 per cent. of the males and 12.6 of the females were definitely ascertained to owe their insanity to drink. A total of over 800 men and 594 for women have been thus rendered incapable of productive work through their own acts, and are being, or have been, supported and clothed at the rate-payers' expense."

With regard to the reputed increase of the drink habit among women, Dr. Jones says: "The proportion of women committed to asylums for insanity brought on by alcohol is largely on the increase and especially among laboring classes. The fact pointed out by the Lunacy Commissioners that whereas the proportion per cent. of alcoholic admissions to total admissions into asylums bears a ratio in the private class of 20.8 males and 9.4 females it is 22.7 for males and 9.7 females among the pauper class, seems to show a greater moral weakness, which prefers immediate gratification to ultimate good, among the poorer classes, as also does it show the increased inhibition which education, the influence of public opinion, and the effects of social ostracism may exercise upon the well-to-do. It is a fact which cannot be blinked that secret drinking is more common among women than men, and more common among well-to-do women than among the poor."

From statistics gathered in every country it is plain that insanity is on the increase, and it would seem to be almost as certain that alcoholism is one of the most fruitful causes of the numerous mental breakdowns. As to the increase of drinking among women, this phase of the situation is undoubtedly chiefly confined to Great Britain. The women of the poorer classes here do not, as a rule, drink to excess. Some lay papers a short time ago published sensational articles asserting that the American women, and particularly the young women of the wealthy class, were accustomed to indulge in strong drinks. These statements, however, were not confirmed, and were probably founded on the fact that a few well-dressed women have been seen imbibing stimulants in fashionable restaurants. The custom is not general, and among the wealthy classes here, as among all classes, drinking is less common than in Europe. Nevertheless it is undeniably true that alcoholism and insanity bear a very definite relation to each other.

Disease in the Philippine Islands.

The somewhat belated report of the Bureau of Health for the Philippines, dated June 15, states definitely the fact already made public that cholera has been decimating the native population of Manila during the past year.

The death rate of Manila for May was 65.81 per thousand, while among the native population it reached the portentous figures of 83.24 to the thousand, or about one person in twelve. Of 1,547 deaths which occurred in May among the residents and 112 among the transients, 445 resulted from Asiatic cholera.

The mortality from the disease among Americans was comparatively small, amounting to only 27.34 per thousand. In the middle of May the virulence of the disease showed an appreciable diminution, so much so, indeed, that the Board of Health raised the quarantine on Manila and the provinces along the railroad. Other neighboring provinces also exhibited a decrease in cholera cases, a result which may be largely attributed to the energetic measures practised by American surgeons.

In Manila beriberi and tuberculosis have, during the year gone by, showed a remarkable increase.

The report publishes interesting statistics of the lepers in the Philippines. The various provinces are reported to contain 3,063 persons afflicted with leprosy. Male lepers number double that of female lepers; 2,092 cases are among adults, and 171 among children; 1,097 of the total number are married. Nearly all the cases are among the Filipinos, there being but forty-three Igorrotes and 220 among the Moros sufferers from the malady. The Board of Health of Manila have displayed a commendable activity in sanitary matters, as may be gathered from the fact that in May 262,500 houses were inspected and 123,092 reinspected, while 31,242 were cleaned. The destruction of rats was also carried on in a wholesale manner. Vaccination was widely practised, over twenty thousand people being vaccinated in May, and sixty-four thousand vaccine points being issued. The result of this was a triumph for vaccination, as there were only nine new cases of smallpox and four deaths from the disease in the month.

Tuberculosis in Public Asylums.

The report of the Tuberculosis Committee of the Medico-Psychological Association of Great Britain and Ireland has recently been issued. The committee has investigated and collected evidence with regard to the isolation of phthisical patients in asylums, and has made practical suggestions. On the whole, the members of the committee find that the charges brought against asylums that tuberculosis was very prevalent in them, and which originated the investigation, have been substantiated. The committee finds that phthisis is prevalent in public asylums to an extent which calls for urgent measures. Furthermore, its members have come to the conclusion that large numbers of patients contract the disease after admission to the asylums, and they proceed to treat of the influences that bear on the asylums' death rate—over-crowding, soil, insufficiency of hours in the open air, defects in ventilation and heating, elevation of asylum buildings, and uncleanly habits. The means of prevention recommended by the committee are set forth as follows: "Early diagnosis of phthisis, isolation of all cases of the disease, limiting the size of future asylums, checking overcrowding, increasing day and night cubic space, restricting the number of beds in dormitories, increased and more thorough natural ventilation for patients, care touching promiscuous spitting, and careful supervision of dietary.

Dr. Crookshank, whose paper was one of the causes of the appointment of a committee to investigate into the condition of asylums, mentions three plans which are possible in the interests of the uninfected patients:

1. With due recognition of the value of ample air space and generous dietary, convert the asylums into large consumption hospitals. This is not the best plan, and it would certainly not be the least expensive.

2. Provide a consumptive block in connection with each asylum, as advocated some years ago by Sir J. Crichton-Browne. In practice this plan when adopted, has meant simply an infirmary for such consumptives as keep their bed and are quiet.

3. Segregate every case of tuberculous disease, whatever the mental condition of the patient. For these segregated patients the open-air sanatorium treatment should be provided.

Statistics in Great Britain—though kept with deplorable laxity—would seem to show that the mortality from tuberculosis among asylum inmates is about five-fold or six-fold more than the ordinary death rate.

It would be interesting to learn whether statistics of our State hospitals bear out the conclusions arrived at by the British committee.

The Milk Committee of the Medical Society of the County of Albany and the Milk Supply.

The above-named committee has recently been testing, bacteriologically, specimens of milk obtained from numerous milk dealers of Albany County. The *Albany Medical Annals*, November, contains an account of the results of this investigation. The milk examined was purchased direct from milk wagons, and all the examinations were made at the Bender laboratory by Mr. A. J. Douglas and Mr. Donald Boyd.

Sixty-five specimens were examined from fifty different dealers. Of these, nine contained pus, and the smear from the sediment of one showed streptococci and staphylococci in abundance. Four of the dealers sold milk in bottles. One driver was seen to fill an empty bottle in a wagon from his can, clap on a cap, and, presumably, sold it as bottled milk. Three counts were so low as to suggest the use of preservatives. In each instance the milk was "dipped" from cans none too clean. One specimen showed the bacteria after five days, and there were only a few moulds on the plates. The summer was remarkably cool, and the counts would have been much higher if the weather had been hot. In spite of this, the number of deaths from diarrhœa in Albany has been very great—so much so, that the health officer in his report, commenting on these deaths, says that "some systematized efforts should be made to improve the milk supply of the city."

Some of the specimens contained some 3,000,000 bacteria per c.c.; one contained nearly 10,000,000 bacteria per c.c., while several specimens showed the presence of more than 1,000,000 bacteria per c.c.

The committee came to the conclusion that the milk now supplied to Albany is not at all what it should be, and urge that steps be taken to insure a purer milk. The committee further gave as their opinion that sanitary milk cannot be sold at the current price—six cents a quart.

The committee, therefore, recommended that a permanent milk committee be appointed which shall have authority from the society to formulate certain standards and conditions, and to grant certificates to such dairymen whose dairies and milk comply to such standards and conditions; and that this milk should be sold for ten cents a quart; and that the members of this society, who shall be kept informed of the names of such dairymen, shall recommend and urge its use in the feeding of invalids, small children, and infants.

The conditions, as regards the milk supply are similar in Albany to those prevailing in many other towns. In order to ensure to the public a pure supply of milk, the essential point is to induce the dairy farmers and dealers to use strictly clean methods in housing and in milking the cows, and in putting the article on the market. If this object cannot be effected at the price charged by some dealers, then it will be advisable to warn the public against buying milk at a cheap rate.

The recommendation of the Milk Committee of the Medical Society of the County of Albany that certificates should be granted to such dealers who comply with certain formulated standards and conditions, is a step in the right direction, and might be adopted in the interests of health by the medical societies and health boards in all towns.

Insanitary House Furnishing.

The main object in furnishing a house with due regard to the health of its inmates, is to provide as few receptacles for dust and for the propagation of microbes as possible. Modern hospitals and sanatoriums are constructed upon this principle. Mouldings, ceiling and wall ornamentation and decoration are entirely dispensed with. The floor is smooth without interstices, guiltless of carpet, and made of a hard, highly polished wood. Every endeavor is made to render the interior of the building aseptic.

Although, perhaps, it would be scarcely desirable that private houses should be regulated, as to their furniture and internal decoration, with the sole view of effecting perfect sanitary results, to the exclusion of all ideas of the beautiful and artistic, yet in many respects public medical institutions might be copied with advantage by householders.

The Greeks and Romans were immeasurably the superiors of the present generation in the planning of houses, which, while pleasing to the eye both inside and out, were devoid of the excess of furniture which it is the delight of the modern rich man to encumber his dwelling places.

We need mention but one feature of up-to-date house furnishing which is a potent menace to health and the principal harborer of dirt and microbes, namely, the carpet.

In *Good Housekeeping*, October, Mr. Wilson points out the possible dangers to health resulting from floor coverings when proper attention is not paid to their care. The statement is made that in a carpeted room in a tenement house, seventy-five germs settled on a three-inch saucer in five minutes, while after sweeping there were 2,700 within the same space.

William Morris, the modern apostle of the beautiful and æsthetic in house furnishing, said that the use of a carpet was excusable only when the floor was in bad condition, but Mr. Wilson thinks that even this is hardly a sufficient reason, for a new floor can be laid over an old one, and he goes on to say: "If one must have carpets, let them be tacked down at intervals of not less than six inches, and with long tacks driven in only at short distances."

The same writer is also of the opinion that the modern steam cleaning of carpets is not so good as that of older days, as airing is desirable. In cleaning a carpet it should be laid on the grass, face down, and then well beaten from the back. This causes the dirt to drop out of the loops where it is so deeply embedded. Brushing the surface with a broom removes the lighter particles, and washing with a cloth wetted in diluted ammonia will both freshen and clean the surface.

Carpets, and especially thick and heavy ones, are, in most instances, uncleanly, unhealthy, and unnecessary. In order to keep them in a sanitary condition, they must be frequently and thoroughly cleaned; and in towns, at least, even in the best houses, this is seldom done. In tenement houses carpets are no more nor less than a positive and constant source of danger to health. There is no need in any room to have the floor completely covered. Large rugs placed where necessary on a sound, well-polished floor answer the purpose as well as a large carpet, looks better, and, above all, are decidedly more healthy. The tendency to crowd a house with furniture and works of art is both vulgar and contrary to the laws of health.

Philadelphia Pediatric Society.—At a stated meeting, held November 11, Dr. L. H. Bernd exhibited a patient with a double mitral disease, probably congenital. The patient was a child a little more than two years old, in whom precordial bulging and a certain degree of cyanosis were observed shortly after birth. The mother had had an attack of rheumatism during the pregnancy, but the child had been free from infectious diseases. The heart was greatly enlarged, and a presystolic and asystolic murmur had been audible, with marked accentuation of the second sound, and also with thickening of the ends of the fingers. In the discussion, the suggestion of a deficiency of the interventricular septum was made. Dr. S. McC. Hamill exhibited a child showing cerebellar symptoms following a fall. The little patient was three or four years old, and it had fallen down a flight of five stairs. In a short while it began to vomit and the gait became ataxic, with a tendency to fall to the left. Improvement took place in the symptoms, and had progressed to almost perfect recovery. Accordingly, inflammation of membranes and brain, as well as hemorrhage into the cerebellum, were excluded, and the condition was looked upon as one of concussion without gross organic lesion. Dr. Hamill also read "A Review of Some of the Older Writings on Maternal Nursing," in the course of which he pointed out numerous views as to nursing and weaning that at the present day appear ludicrous. Dr. Theodore LeBoutillier reported a case of chronic intestinal indigestion, with an acute exacerbation and meningismus. Consciousness was lost and convulsions occurred, but recovery ensued as the gastrointestinal derangement and the associated intoxication were relieved.

News of the Week.

Recrudescence of Cholera in the Philippines.—A despatch to *The Sun* from Manila, dated November 12, states that cholera has broken out in the Fifth Infantry, which is quartered in Manila. Seven enlisted men have already died from the disease, and a dozen others are ill. Cholera has reappeared at Maraquina, seven miles from Manila, along the rivershed which supplies that city with water. Orders have been issued reestablishing a military quarantine to guard the sources of supply and prevent infection of the water supply. It is doubted that the recrudesence of the disease in Manila will prove serious.

School Infection.—In the recently published report of the corps of medical school inspectors on their work from the first week in September, when the schools opened, until October 25, it is stated that 1,027,835 inspections were made, and that 19,453 children were excluded—in most cases only temporarily—principally on account of the following diseases: Parasitic diseases of the head, 11,396; contagious eye diseases, 6,667; chickenpox, 19; mumps, 29; whooping cough, 68; scarlet fever, 7; diphtheria, 4; measles, 12; various forms of skin diseases, 443. In Brooklyn, during the week ending November 8, 412 had to be excluded for the following causes: One case of diphtheria, five cases of whooping cough, nineteen cases of mumps, 147 cases of contagious eye diseases, 171 of parasitic diseases of the head, three cases of chickenpox, sixty-one cases of skin diseases. These children were all in attendance at the schools at the time of inspection. The total number of children examined in the parochial and public schools was 97,333.

Combining against Mosquitos.—Some of the residents of Morristown, N. J., have formed a corporation for getting rid of the mosquitos of Speedwell Pond. Most of Morristown is built over heaps of glacial stone, which affords drainage. But some railroad embankments and a partial filling in of the lake have caused the forming of a great swamp near Speedwell, where the mosquito flourishes. Experts report that the only way to make the lake sanitary is to dry it up. The company has been capitalized at $25,000, of which one-half has been paid in. The only dividends looked for are in the shape of increased health and comfort resulting from the absence of mosquitos.

Rush Medical College and Chicago University.—It is said on we do not know what authority that the enormous sum of $8,000.000 will be spent by the University of Chicago for building up Rush Medical College. This will be the result of making Rush an organic part of the university, which will be accomplished at the end of the scholastic year if the Rush trustees raise $1,000,000. The expenditure of the sum mentioned will not be begun immediately, but it will be accomplished within the next decade. Several Chicago multimillionaires are mentioned as probable donors of the million needed by Rush, and the unfailing Rockefeller well is said to be ready to gush up the eight millions.

American Rontgen Ray Society.—The third annual meeting of this society will be held at the Sherman House, Chicago, on December 10 and 11. The president of the society is Dr. G. P. Girwood of Montreal, the secretary, Dr. James B. Bullitt, 205 West Broadway, Louisville, Ky. The Eastern, Western, Central, and Southern Passenger Associations have granted a one and one-third fare rate, provided that one hundred persons buy tickets on this plan.

Christian Science and Contagious Disease.—Mother Mary Baker Eddy is not so big a fool as many of her worshippers, and has advised readers and healers throughout the land to fight shy of contagious disease. "Until public thought," she says, "becomes better acquainted with Christian Science, the Christian Scientists shall decline to doctor infectious or contagious diseases," though how they are going to diagnose a think of pimples from a claim of smallpox she doesn't say. Perhaps the healers will do what many of them have long had the custom of doing—call in a physician to make a diagnosis and prognosis, and then dismiss him and think and protest and fight the claim. In a recent issue of the *Christian Science Sentinel* the editor says healers have a perfect right to treat disease under the constitution which provides for the free exercise of religion, but he orders them not to fool with contagious maladies. When it comes to that, he says "a different phase of the question is presented in the matter of reporting cases of so-called contagious diseases, in keeping with the law or regulation which has been enacted with a view to conserve the public welfare, and so long as the law demands that such cases be reported, Christian Scientists shall be prompt and unfailing in their obedience, and give the public the benefit of any serious doubt which may attend the classification of disease."

Mutter Lecture on Surgical Pathology of the College of Physicians of Philadelphia.—The Mütter Lecture for 1902 will be delivered in the Hall of the College of Physicians, N. E. corner of thirteenth and Locust streets, on Tuesday, December 2, at 8 P.M. by Louis A. LaGarde, Major and Surgeon, U. S. Army. Subject: "Poisoned Wounds by the Implements of Warfare."

Lectures on Orthopedic Surgery.—A course of free clinical lectures on orthopedic surgery will be delivered by Dr. Hibbs at the Orthopedic Dispensary and Hospital, 126 East Fifty-ninth street, on Tuesday and Saturday afternoons, at four o'clock, from November 25 to December 27, inclusive.

Public Lectures on Scientific Subjects at the College of Physicians and Surgeons.—The following lectures on scientific subjects of interest to students and teachers of medicine will be given by officers of Columbia University. On successive Wednesdays at 5 o'clock in the Lower Lecture Hall, College of Physicians and Surgeons, entrance at 437 West Fifty-ninth street, officers, alumni, and students of the College of Physicians and Surgeons are invited to attend these lectures. Admission is without ticket up to the limit of the Lecture Hall. November 26, Bashford Dean, Ph.D., Adjunct Professor of Zoology, on "The Beginnings of Certain Characteristic Structures of Man"; December 3, Edmund B. Wilson, Ph.D., LL.D., Professor of Zoology, on "The Phenomena of Cell Division in Relation to Some Problems of Biology and Medicine" (illustrated); December 10, Lucien Marcus Underwood, Ph.D., Professor of Botany, on "The Relation of Botany to Materia Medica"; December 17, Livingston Farrand, A.M., M.D., Adjunct Professor of Psychology, on "Nervous and Mental Diseases among Savage Races"; January 7, J. Livingston Rutgers Morgan, Ph.D., Adjunct Professor of Physical Chemistry, on "Osmotic Pressure and Ionization" (illustrated); January 14, Edmund Howd Miller, Ph.D., Adjunct Professor of Analytical Chemistry, on "Some Analytical Applications of Ionization"; January 21, Marston Taylor Bogert, A.B., Ph.B., Adjunct Professor of Organic Chemistry, on "Synthetic Organic Medicaments"; January 28, James McKeen Cattell, Ph.D., Professor of Psychology, on "Physical and Mental Fatigue"; February 4, James Furman Kemp, A.B., E.M., Professor of Geology, on "Geological Factors in Problems of Water Supply" (illustrated); February 11, Richard Elwood Dodge, A.M., Professor of Geography in Teachers College, on "The Weather Phenomena of the Eastern United States in Their Relation to Bodily Health" (illustrated); February 18, Gary N. Calkins, Ph.D., Instructor in Zoology, on "The Protozoa in Relation to Modern Problems in Biology"; February 25, Henry Fairfield Osborn, Sc.D., LL.D., Da Costa Professor of Zoology, on "Methods of Exploration for Fossil Mammals and Reptiles in the Rocky Mountain Region" (illustrated); March 4, Frank Leo Tufts, Ph.D., Tutor in Physics, on "Some Recent Researches on the Relation of Electricity to Matter" (illustrated); March 11, William Hallock, Ph.D., Professor of Physics, on "Some Phenomena of the Molecular Mechanics of Liquids" (illustrated); March 18, Franklin Henry Giddings, Ph.D., LL.D., Professor of Sociology, on "Vital Statistics" (illustrated); March 25, Henry E. Crampton, Ph.D., Adjunct Professor of Zoology, on "The Problems and Results of Experimental Embryology" (illustrated); April 1, Alexander P. Anderson, Ph.D., formerly Curator of the Herbarium, on "Starch, Its Properties and Uses" (illustrated).

Coroner's Wisdom.—In a fulness of knowledge, and with characteristic assurance, the Coroner's assistant in the city of Philadelphia has ventured to reject the diagnosis of hydrophobia made by two reputable physicians, stating that "there is no such thing as hydrophobia," and proffering the services of his office for instruction on the subject.

College of Physicians of Philadelphia, Section on General Medicine.—At a stated meeting, held November 10, Dr. Chas. K. Mills presented a patient exhibiting symptoms of brain tumor in whom a blow with a hammer over the angle of the lower jaw was followed by contraction of the risorius muscle. Drs. Wm. G. Spiller and J. H. McKee presented "A Patient with Paraplegia Following Lumbar Puncture for Cerebrospinal Meningitis." The patient was a colored child about four years old and the symptoms of paraplegia developed in such close sequence upon the puncture of the spinal canal that there seemed no doubt that the two were related as cause and effect. Great improvement followed treatment with massage and electricity in conjunction with active movements of the affected members, while the child was placed in a bath of warm water for a short time once or oftener daily, it being believed that such movements are more readily executed in water than on the bed. Dr. Wm. G. Spiller read a paper entitled "Traumatic Lesions of the Brain in Relation to Operation." He related a series of cases of injury to the skull in some of which operation had been performed promptly with brilliant results with regard to both immediate and permanent success, and in others of which disaster of varying degree had followed in consequence of postponement or abandonment of operation. The subject was discussed also by Drs. Mills, Frazier, and Burr. Dr. J. H. Musser presented "Notes of a Case of Leprosy." He reported the case of a young Cuban girl at school in this country who presented symptoms suggestive of rheumatism, but which in the further progress of the case were found on return home and examination by experts to be dependent upon leprosy. Dr. Alfred Stengel read "A Preliminary Report of Two Cases of Pulmonary Thrombosis in Typhoid Fever." In the one case the condition was recognized only upon postmortem examination, while in the other it was diagnosticated during the life of the patient, while after death bronchopneumonia, pulmonary infarction abscess of the lung and pleurisy in addition to characteristic intestinal changes were found, and typhoid bacilli were isolated from all of the lesions. The case was marked further by a notable diminution in the number of leucocytes in the blood.

The Suffolk County (N. Y.) Medical Society.—The annual meeting of this society was held at Patchogue, L. I., on Saturday, November 1. Papers were read by Dr. P. F. Chambers of New York City on "The Gynecologist's Position in Medicine," and by Dr. W. B. Heyman of the Cental Islip State Hospital on "Some Practical Points Relating to Mania." A committee, consisting of Drs. A. H. Terry of Patchogue, W. H. Ross of Brentwood, and M. B. Lewis of Easthampton, was appointed to arrange a tariff of fees. The secretary of the society is Dr. P. Van Benschoten Fowler of Centre Moriches.

A Monument to Esmarch.—The eightieth birthday of Prof. Friedrich v. Esmarch will be celebrated in Kiel on January 9, 1903. In honor of this event a monument will be erected in Tönning, v. Esmarch's birthplace, the unveiling of which will take place some time next summer.

Dr. Herman Knapp has resigned from the chair of ophthalmology at the College of Physicians and Surgeons, Medical Department of Columbia University, and has been appointed by the trustees of the university Emeritus Professor of Ophthalmology.

Popular Lectures on Tuberculosis.—The Committee on Tuberculosis of the Charity Organization Society last night, in the Charity Organization Society's building, Twenty-second street and Fourth avenue, decided to give lectures the first Monday in every month in the assembly hall of the United Charities Building, and also in public school buildings, on the prevention of consumption. The lectures will be in English, Italian, and Yiddish, and possibly also in Chinese. The first lecture was delivered on November 10 by Dr. J. H. Huddleston, the subject being "Germs of Consumption—What They Are and What They Do." Others of the course will be by Drs. Biggs, Janeway, Knopf, Trudeau, Jacobi, and Bryant, and Secretary Devine of the Charity Organization Society.

The New York University Loses Its Laboratory.—The Appellate Division of the Supreme Court has handed down a majority opinion sustaining the decision of Justice Truax in directing the New York University to reconvey to the Medical College Laboratory of the city of New York the premises which were deeded over to the university in 1897 in accordance with a plan for combining the laboratory and the university. The property in question is on the south side of Twenty-sixth street, 150 feet east of First avenue, and its value, as stated in the decree, is from $150,000 to $200,000. According to the findings of the Appellate Court, the transfer to the New York University from the Medical College Laboratory by deed dated February 8, 1897, was a conveyance in trust or upon conditions. Both the property and the entire control of all matters relating to medical affairs were to be vested in a medical committee, and, although not so stated in the deed, such were understood to be the conditions of the transfer. The Appellate Court finds that the New York University violated the conditions of the trust, and directs that the property be deeded back to the grantor.

A New Name for Christian Science.—A Christian Science reader or healer "passed on" from Toledo recently, and the unfeeling "claim" made in the certificate was that death was due to autointoxication.

A Medical Governor of Rhode Island.—Dr. Lucius F. C. Garvin of Lonsdale, the newly-elected Governor of Rhode Island, is a native of Tennessee, he having been born in Knoxville, that State, in 1841. He is a graduate of Amherst College, in the class of 1864, and of the Harvard Medical School in 1867. He was elected on the Democratic ticket.

Increasing Birth Rate in France.—After a long period of steady decline, the birth rate in France is beginning to rise. The report on vital statistics for 1901, recently published, shows an increase in population of 72,398, against a decrease in 1900 of 25,988. There was a slight proportional decrease in the death rate, but the larger population is due mainly to an increase in the number of births.

Faith Healing and Fraud.—A concern in Nevada, Mo., styled the American School of Magnetic Healing, has for some time been conducting an extensive "absent-treatment" business, undertaking, upon payment of the necessary fees, to heal disease in anyone, anywhere, at any distance, by mental process. After an investigation by inspectors, the Postmaster-General issued an order declaring the business a fraudulent one, denied the concern the use of the mails on that ground, and directed the return of all mail matter addressed to the school. The business manager of the concern appealed to the local court against this decision, and being denied there took the case to the Supreme Court. This tribunal has decided that the Postmaster general had not the right to say whether any form of treatment was or was not capable of curing disease, and that therefore he erred in branding the business of the "magnetic healers" as fraudulent and depriving them of the use of the mails. Justice Peckham, who handed down the decision, and those who concurred with him in it seem, from the published reports of the case, to have missed the point of contention. The Postmaster-General did not, in effect, pretend to pass upon the efficacy of any form of treatment, he merely insisted that the business of that particular concern was fraudulent. According to Acting Assistant Attorney-General Christiancy, the principal inducement made in all the advertisements and circulars of the American School of Magnetic Healing was that for the sum of $5 a month Prof. Weltmer would devote fifteen minutes each day in special and particular thought for the patient remitting him the fee in order to effect a cure. But the income in fees amounted to $2,500 a day, which made it an utter impossibility for Weltmer to devote fifteen minutes each day to each person, and, either in despair of carrying out his promise or for some other reason, he went to Manitou Springs for a long vacation, and during other periods of time was lecturing throughout the country, paying no attention to his absent-treatment business. The parties in the scheme were indicted for using the mails to defraud, and Weltmer pleaded guilty to the charge at Kansas City, Mo., April 26, 1901, and was fined $1,500.

The Late Dr. M. J. Asch.—At a stated meeting of The Medical Association of the Greater City of New York held at the New York Academy of Medicine November 10, 1902, the following report was received and adopted: Morris Joseph Asch, M.D., died at Irvington-on-Hudson October 5, 1902, in his seventieth year. He was a native of Philadelphia, where he took his degree in arts at the University of Pennsylvania in 1852, and in medicine at Jefferson Medical College in 1855. Through the civil war he served with distinction on the staff of Gen. Sheridan. For upwards of thirty years, and until his retirement less than two years ago, he was engaged in active practice in New York, where he gained a large following and many friends. In 1872 he became a surgeon and afterwards a consultant at the New York Eye and Ear Infirmary, and he served in similar positions in the throat department of the Manhattan Eye and Ear Hospital from the year 1879. For several years he held a professorship of Laryngology at the New York Polyclinic. He was one of the original Fellows of the American Laryngological Association, and in 1892 received the well-deserved honor of election as its president. His contributions to literature were frequent and valuable, consisting for the most part of clinical reports gathered from his unusually wide experience. He was a member of many social and scientific bodies, in all of which he won the friendship and esteem of a large circle. By those most intimately associated with him in hospital and clinical work he will be remembered for his devotion to duty, his keenness in diagnosis, and his manipulative skill. His chief title to fame with the profession at large rests upon his careful elaboration of an operation for the correction of deflections of the nasal septum, with which his name will always be connected. Whatever may be the general opinion of the Asch operation, whatever improvements and modifications it may hereafter undergo, the fact remains that he succeeded in grasping the principles which underlie the successful management of this obstinate deformity and in proposing certain technical details of marked value. His charm of manner, his amiable disposition, and his kindness of heart combined to endear him to everyone with whom he came in contact, whether patient, friend or colleague. Those nearest to him will always recall his attractive personality. To the world his career and character will stand as models worthy of emulation.

(Signed) Charles H. Knight, Chairman.

Bucks County (Pa.) Medical Society.—At the annual meeting held at Doylestown on November 5, the following officers were elected for the ensuing year: *President*, Dr. Evan R. Groom of Bristol; *Vice Presidents*, Drs. William S. Erdman of Buckingham, and Charles B. Smith of Newtown; *Secretary*, and *Tresaurer*, Dr. A. F. Myers of Blooming Glen.

The Late Dr. Abel Mix Phelps.—The following is the report of a special committee of the Medical Association of the Greater City of New York. Dr. Abel Mix Phelps, whose death occurred on October 6, 1902, was born as Alburgh Springs, Vt., January 21, 1851, and obtained his medical degree in 1873 from the University of Michigan. After practising a number of years at Chateaugay, New York, he spent some time abroad, devoting himself especially to orthopedic surgery. In 1885, shortly after his return to this country, he was called to the Chair of Orthopedic Surgery in the University of Vermont. Later, he occupied for a number of years the same chair in the University of New York. As a further recognition of his labors in this branch of surgery, he was, in 1894, elected President of the American Orthopedic Association. In 1901 he became President of the Medical Society of the State of New York. At the time of his death he was Visiting

Surgeon to the City Hospital, Blackwell's Island, and was Professor of Orthopedics in the New York Post-Graduate School. Dr. Phelps was a man of enthusiasm and force, great originality, and firm convictions. Lucid in thought and expression, a bold and skilful operator, he was also a successful teacher and leader in his chosen field, operative orthopedics. Early recognized as a pioneer, his name will be held in honorable esteem wherever scientific orthopedics is practised. Those who were associated with him more intimately knew the tender side of his nature. In a wider circle he will be best remembered as an honest and true friend.

Obituary Notes.—Dr. Obadiah Newcomb of this city died suddenly of apoplexy on November 14, aged eighty-one years. He was born in New York City on January 23, 1821. He was graduated as Bachelor of Arts from Columbia College with the class of 1840, and later received the degree of M.A. from the same institution. He studied medicine at the Medical College of Castleton, Vt., and was graduated therefrom in 1850. Dr. Newcomb was one of the first physicians of this city to adopt homœopathic practice. For many years he carried on a large practice, continuing up to the day of his death, and gained a reputation for sterling personal qualities as well as for his professional skill.

Dr. William H. Crim of Baltimore, one of the most prominent physicians in Maryland, for many years Surgeon-Major of the Fifth Regiment, Maryland National Guard, and a noted collector of antiques, died suddenly from heart disease on November 15. He was born in Loudoun County, Va., fifty-seven years ago, and was graduated from the University of Maryland School of Medicine in 1870.

Dr. William H. Kimberlin of Kansas City was shot and killed on November 11 by a patient upon whom he had operated for cataract and who had persuaded himself that the operation had injured his sight. After shooting the doctor, the man, a policeman, killed himself. Dr. Kimberlin was fifty-eight years old and was a graduate of the College of Physicians and Surgeons, Kansas City, in 1884, but had previously studied the diseases of the eye in several institutions in this city for several years before taking his degree. He was one of the best known ophthalmologists in the West.

Dr. William Henry Haynes, president of the Brooklyn Society for Neurology, died on Saturday, November 15, at his home in Brooklyn. Dr. Haynes was born in New York City forty-six years ago. He was educated in the College of the City of New York and in the medical department of New York University in 1876. For fourteen years he practised in the old city of New York and then moved to Brooklyn. He was a member of the Kings County Society, the Brooklyn Medical Society, the Neurological Society and the Pathological Society and was attending physician to the Central Hospital and assistant neurologist to the Eye and Ear Hospital.

Dr. Frank Livermore died on November 18, at his home in this city, aged sixty-two years. He was graduated at the University of Paris in 1868, and had been engaged in practice in this city since the early seventies. He was a member of the Medical Society of the County of New York and of a number of social clubs and other non-medical organizations.

OUR LONDON LETTER.

EARL ROBERTS ON THE PROFESSION—PATHOLOGICAL SOCIETY—CLINICAL EXHIBITION—A NEW SOCIETY—A QUACK CONDEMNED TO PENAL SERVITUDE—ACCIDENTAL POISONING IN DISPENSING—DINNERS—ITEMS

(From Our Special Correspondent.)

London, October 31, 1902.

Earl Roberts yesterday afternoon distributed the prizes at St. George's Hospital. The genial Field Marshall made a characteristic speech, which is well calculated to raise the public estimate of the medical profession, and especially of our army brethren. He asked his audience to remember he was only a simple soldier, not a savant, but no section of the public could be more interested in the work of their noble profession, and none owed a deeper debt of gratitude to those who, by their ,constant study, earnest inquiry, and careful experiments learned and taught how to heal the sick and tend the wounded, to alleviate pain and maintain health in camps and quarters. In a long and arduous campaign there were always more victims to disease than to shot and shell. In proof of this Earl Roberts quoted some figures from Kinglake's "Crimea." In twenty months the French had 23,25 cases of scurvy, over 1,100 a month, and in our own army on the last of February, 1855, out of a force of 30,919, there were 13,608 in hospital. Kinglake also said that, of 48,742 cases admitted to hospital in a certain period, nearly three-quarters were zymotic, and, in a sense, preventable Comparing these figures with those of the late war in South Africa, Earl Roberts said that in two and a half years we sent out 400,000 men, and for some time had an average of 250,000 in the field. The total deaths from sickness up to May 31 were 13,750, and during the war 66,500 were invalided, of whom 500 died, they being included in the 13,750 mentioned; 5,879 were discharged from service as unfit, and 959 are still in hospital, the rest having returned to duty. Those striking figures, his Lordship continued, showed the great improvement that had taken place, and that was due to the march of medical science and the personal devotion of the medical officers and the nurses under them In expressing gratitude for these achievements, he voiced the opinion of the army, and the appreciation of their work by soldiers might be an incentive to their efforts. Many people were inclined to slack off after examinations were over, but if great results were to be obtained there must be no slacking off—least of all in the great profession of medicine and surgery. Real and higher education began when they left their class-room for the arena of the world. Let them take their work in earnest from the commencement, and never loiter. Those who loitered would be left behind, for in their profession there was no finality.

Sir J. Burdon Sanderson opened the session of the Pathological Society with an interesting address on recent discoveries relating to immunity—not such as that of Professor Welch in his Huxley lecture, but rather an attempt to put into language which would have been intelligible to a student twenty years ago the technical language necessarily employed in dealing with complicated experimental data. He sketched the progress made as to the etiology of inflammation and tubercle in the ten or twelve years preceding Koch's discovery of the bacteriological method, and then Nuttall and Buchner's discovery of the anti-infective property of the liquor sanguinis, and Behring's of antitoxins. He passed on to the evidence that bacteriolysis comprises two actions, one of which is specific, the other non-specific, and Bordet's work showing the normal resistance of blood discs and bacteria to the specific is counteracted by the non-specific action. Afterward he touched on the researches of Muir (Glasgow), Roger (Paris), Mallory (America), on the protective action of the bone marrow, the spleen, and the lymphatics. After the address Messrs. Abbott and Shattock recorded in great detail a form of macroglossia, not previously described, in a girl of four years. The tongue protruded from the mouth at one and one-half years. On admission, in August, 1900, there was general enlargement on the left side, and in its posterior part a circumscribed tumor. The whole left side of the face was puffy, as was the neck also, where a large swelling below the jaw extended from the mid-line to the sternomastoid muscle. The anterior two-thirds of the left side of the tongue were removed by V-shaped incisions, but a portion of the circumscribed growth was left behind At a later operation on the neck two masses of worm-like coils of semi-transparent white cords were removed. Facial paralysis followed. When seen last summer the tongue lay in the mouth and was fairly symmetrical, the facial paralysis was less, the eye could be closed. In the neck there had been no recurrence of the cords at the site of the operation, but similar ones had formed in the neighborhood. Dissection of the tongue showed all the nerves to be enlarged and so increased in length as to be in serpentine or transverse folds; in the divided posterior surface the muscular substance was scarcely recognizable on account of the enlargement of the nerves lying in it. Microscopic sections showed that enlarged nerves occupied most of the sectional area, the bundles of muscular fiber being widely separated by them.

Among the cases shown at the Clinical Society were a boy of seven years and his sister of one and a half years with progressive spinal muscular atrophy of the Werdig-Hoffmann type. Both seemed healthy up to about twelve months of age. Dr. Savill's case of leprosy in aboy of sixteen, to show the improvement under chaulmoogra oil. There was a girl of fifteen years with displacement of the heart due to chronic pleurisy; the impulse is most easily felt in the fifth right interspace. A girl of eleven years ten and one-half months, from whom Mr. Malcolm removed a tumor of the right kidney in 1892, thought to be malignant adenoma. She has enjoyed fair health since. A man of forty years, recovering from herpes zoster, which was followed by facial paralysis, shown by Dr. Stanley Barnes.

More than one attempt to establish a therapeutical society here has failed. There is now a somewhat more likely plan in process of gestation. Perhaps I should rather say the infant has been born, though at present it is not very lively, but healthy enough, and promises to grow rapidly. The presidency has been accepted by Sir William Thistleton-Dyer, F.R.S., K.C.M.G., the distinguished director of Kew Gardens. All qualified practitioners are eligible for election as Fellows, as also are other persons interested in the subject. The subscription is a modest one—half a guinea. This is because the expenses will be very low, the Apothecaries' Company providing a room for the meetings in their hall. The company may be congratulated on its decision to do something to promote scientific investigations, for of late years it cannot claim to have been as useful to the profession as it was at one time.

The idea of the new therapeutical Society is to become a center where travelers may come and report any finds they may have met with in the shape of medicinal substances or appliances used in the countries they have visited, and any information as to methods of treatment employed by the races with which they have come in contact. Explorers naturally go to the Geographical Society with the record of their general work, but matters medical are scarcely within its scope. An account of medical plants and other things may well, therefore, be brought to the therapeutical society, which may well be considered as destined to promote the study of materia medica.

Unqualified practice, though so rampant, occasionally leads to serious consequences. A man named Herring took a house and put up a plate calling himself Hoffmeister, M.D. and M.S. An inquest had to be held on a woman he had given drugs to, but who had strangulated hernia. Herring swore he was qualified, but later was prosecuted for perjury and for gross criminal negligence. The evidence was that the prisoner was formerly a clerk, left his employment under unfavorable circumstances, and for years led a life of gross imposture. A verdict of manslaughter was returned, and the judge said "he could not imagine anything more dangerous than that an impostor should take on himself, for the sake of money, the care of the sick and subject them to his mismanagement. As a deterrent to others he must pass a severe sentence, which was that the prisoner be kept in penal servitude for five years." The indictment for perjury was thereupon dropped. The judge's decision in this case is one of the greatest importance to the profession and will be a wholesome warning to quacks.

A sad case of poisoning by error led to an inquest at Birkenhead. A doctor mixed some powders for two children and, while doing so, left for a moment to question the mother. On returning to complete his dispensing, it is supposed that he inadvertently took the strychnine bottle instead of santonine. One of the children died with symptoms of strychnine poisoning, on which the doctor gave an antidote to the other and it recovered. The doctor took one of the doses himself, to make sure that he had not mixed the wrong drug, and suffered severely from the poison. That strychnine bottle ought not to have been near the santonine nor amongst the less dangerous drugs.

In a magazine article Dr. J. Vaughan says that there is a valley in Hampshire where poisonous plants flourish exceedingly—henbane, hemlock, hellebore, bryony, and, above all, belladonna. This last not in single plants here and there, but in thousands. He does not give the precise locality of this "veritable valley of Hinnom," where "rabbits fatten on the leaves and acquire, it is said, a superior flavor." Many have supposed that these dangerous plants were decreasing in England, and certainly the accidents have not been so numerous as formerly, though this may be due to the spread of knowledge among children. Atropa belladonna used to be plentiful in the Isle of Wight, but you never meet with it now—perhaps because the people, aware of its poisonous nature, have intentionally uprooted every plant they met with. This is certainly the case in some localities.

A tablet was placed last week in the public library of Ealing in memory of the late Professor Huxley, who was born in that district.

At the annual dinner of the Society of Anæsthetists, Sir H. G. Howse, president of the Royal College of Surgeons, testified to the great progress made. He said in his student days a mortality of 1 in 200 was spoken of as not remarkable, and now it is not more than 1 in 6,000. Other speakers emphatically testified to the value of the society.

The annual meeting of the Association of Public Vaccinators was held on Saturday. In the evening the members dined together, and Dr. Copeman gave a lantern demonstration of the most recent work on vaccina and variola.

The County Council has prolonged for a further two months the time in which varicella is to be notified. On Tuesday two cases of smallpox were admitted to the hospitals of the Asylums Board, the first admissions for a week. There were then twenty-nine cases under treatment.

AN ARMY MEDICAL SCHOOL.

To the Editor of the Medical Record:

Sir: Referring to the paragraph headed "Shortage in the Army Medical Corps," appearing in a recent issue of the Medical Record, relative to the severity of the examination, etc., I can say that while I am in sympathy with the Army Medical Corps and their desire to regain their former relative standing with other army officers, yet I do not think it proper that good and efficient men should be rejected simply to establish a basis for argument that their are no temptations to enter the service under existing regulations. It seems absurd that out of a class of four presenting themselves for examination not one could be found physically qualified to proceed with the mental examination, and I dare say, according to reports, that other classes have met with the same fate. Notwithstanding a rejection on account of height is a perfectly legitimate one in view of regulations to that effect, still it seems ridiculous to think that a physician of sixty-three and three-quarter inches in height could not administer to the needs of the sick equally as well as his brother physician of sixty-four inches.

As a remedy for the shortage of army physicians, why not establish a military medical college on the same basis as the cadet school at West Point. Admit young men for a course of, say, four years, and after graduation make assignments to the army in the same manner as now done for commissioned officers of the infantry and other branches. This would, in a great measure, obviate the present trouble of securing men for the Army Medical Corps. Competent professors detailed from among the army medical officers, in addition to furnishing the necessary medical education, would tend to better fit young men for military service by their association and preliminary introduction into military life.

W. Newburn, Jr., M.D.

New York

THE MEDICAL MISSIONARY'S WORK IN KOREA.

To the Editor of the Medical Record:

Sir: For those who do not know what a medical missionary is called upon to do, I will say that during the past year I spent five months in answering calls to see Americans and British who were in need of my services, though part of it was spent where I went to rest but had to remain to work, the doctor resident there being sick and forced to leave.

One of the trips was, in midwinter, to see a man with malignant smallpox. I was two days and a night through snow and storm with the temperature from 20° to 27° below zero. The journey was made in a chair carried by four men, with others to change about with them. Another urgent call requiring a hundred-mile trip in a chair was to see a missionary sick with typhoid fever.

Another trip lately was out some ten miles to relieve a native woman of a dead child—arm presentation. From the time that the chloroform was commenced until the work was finished and the woman answering a question was thirteen minutes. The protruding arm was amputated, then the head was cut off, then the other arm was removed, and the body was delivered with the blunt hook. This was done this way because it was the easiest. She made an uninterrupted recovery. There was no internal after-treatment, though the placenta was peeled out with the fingers. A cleansing douche would have been in order, but no clean water was to be had. The uterus and vagina were simply cleaned out with the hand Quinine, morphine, and acetanilid, in small doses, were given. This, with one dose of ergot, was all the medication. I mention this case only as one of several, all with uniform recoveries.

I have a severe case of ephithelioma, involving most of the cheek. It is almost too extensive to operate on with hopes of removing it entire, so I am trying injections of nuclein, together with direct concentrated rays of sunlight. Though the case has been under treatment only a few days, there seems to be a noticeable improvement.

J. Hunter Wells, M.D.

Pyengyang, Korea, Sept. 6, 1902

THE MATTISON METHOD IN MORPHINISM.

To the Editor of the Medical Record

Sir: In a recent number of the Medical Record reference was made to a paper read by Dr. Ivey of Lenoir at the last meeting of the North Carolina State Medical Society on the above topic—a method that, after large experience, I make bold to claim in advance of all others in cases fitted for its use, to effect two leading objects—minimum length of treatment and maximum freedom from pain.

Dr. Ivey treated his cases with larger doses of bromide than I use. In most cases, I think, the smaller initial dose—10 grs. semi-daily, 10 A.M. and 10 P.M. (not four o'clock), and increasing it 20 grs. daily, reaching a maximum of 70 to 100 grs. twice a day—the better plan.

In my book—"The Treatment of Opium Addiction," 1885—the initial dose was 60 grs. with daily increase, as stated, for seven days, but larger experience proved the decimal plan—10 grs. semi-daily, with 10 grs. increase in each dose per day for ten days—to be better. The aggregate amount is much the same, but the longer time of taking—during which the opiate is withdrawn—has been free from any untoward mental effect of the sodium, which, though mild, was sometimes noted under the old régime. Some cases do not require it; others, seven or eight days. Each case is a law unto itself, and in all cases the bromide should be used, as Opie mixed his colors—"with brains."

Dr. Ivey did not use codeine and trional. They are of much value. With them, we do not put patients to bed, and, as a rule, a nurse is not needed. If given with care, there need be no fear of codeine. While not wholly free from risk of tolerance, it is vastly more so than is morphine, heroine, or dionine.

With most patients, a semi-daily dose of the usual opiate—as stated by Dr. Ivey—will not suffice. Three or four are better, and my usual plan is to give at seven, twelve, five, and ten o'clock.

Dr. Ivey said wisely as to the need of post-active care:—It is of much moment: in many cases *a sine qua non*. A system battered by years of morphine excess will not come back to its normal in a few weeks or months. Not the immediate, but the remote future of my patients gives me most concern. Specially true is this of medical men, who constitute 70 per cent. of those who honor me with their care. With the coming of better health, when the opium load is lifted, comes the risk of too early return to work. This is the rock on which the doctors founder. This, with lack of hygenic care and favoring environment—which, continued months, or even years, is essential to a lasting cure—is, I take it, the great factor in recurring morphinism among medical men.

En passant, two so-called methods which have had some vogue, may be noted. One is the giving of bromide in large doses to the extent of an ounce daily, for three or four days, during which the opiate is ended. Dementia—for months—or fatal lung œdema has been known to follow.

The other is the frequent subcutaneous giving of 1-10 c to 1-50 gr. hyoscine hydrobromide. This palsies and crazes, demands constant vigil, and compels strychnine or spartein to avert cardiac failure or death. There is no place in sound therapeutics for such measures, which should be denounced as irrational, unscientific, inhumane, and dangerous. I warn the profession against them.

J. B Mattison, M D.

Brooklyn

Progress of Medical Science.

The Boston Medical and Surgical Journal, Nov. 13, 1902.

A Fatal Case of Mandrake Poisoning.—A. W. Buck, because of the rarity of fatal cases of mandrake poisoning, tells of a case of recent occurrence. A lady was given a dose of what was supposed to be liquorice powder but was subsequently found to be mandrake. Vomiting and purging followed, with chilly sensations. A physician was called, who ordered a small amount of bromide of soda, bicarbonate of soda, and syrup of ginger, of which prescription the patient took three doses. She then appeared to be resting quietly, was drowsy and hard to rouse, but seemed to be doing well. She slept through the night, in the morning could not be awakened, and died at eight o'clock.

A Probable Myxofibroma of the Nose.—Seabury W. Allen reports the case of a man who twenty-two years ago noticed a slight protrusion of the lower left eyelid, a soft, friable, easily bleeding tumor appearing at the left nostril some months later. From that time the growth has been slowly progressing, and has lately emerged from the mouth, having come through the hard palate and separated the upper teeth. The face as shown by illustrations, has lost almost all semblance to the human. There is difficulty in articulation and in eating, and, until recently, there has been a continual discharge of saliva and mucopus, the latter coming from the center of the mass, which has sloughed away, leaving a cavity as large as one's fist. Operation is not possible. Seven *x*-ray exposures have greatly diminished the odor and the amount of the discharge, and the patient and his family think that the mass, as a whole, has shrunken.

Journal of the American Medical Association, Nov. 15, 1902.

Pneumonia; Its Incidence, Mortality, and Prophylaxis.—J. J. Walsh notes the increase of the disease, and believes that while the directly contagious nature of the malady is still a matter of dispute, there is always an element of contagion-danger in a pneumonia case, and that certain protective and prophylactic measures are called for. Practically the same plans now followed with tuberculous and typhoid patients should be carried out in case of pneumonia. He calls special attention to the danger lurking in dust, crowded assemblies, gas leakage, and defective drainage.

Renal Insufficiency in the Tropics.—The views advanced by J. C. Minor are derived from personal experience in the Philippines. He believes that military regulation should be so altered as to allow men to drink as much water as they desire, provided, of course, it is good water. His conclusions are as follows: (1) Whether the systemic disturbance causing the usual disorders peculiar to the tropics be uric acid or faulty metabolism, or both, the kidneys in the tropics do not perform their share of the work of emunction. (2) The reason for this renal insufficiency in the tropics is that the tide of water (the necessary solvent vehicle for urinary solids) pours through the skin so rapidly that the volume of circulation is so correspondingly diminished that waste products are stranded in those tissues most favored by the weakened flushing force for stasis. (3) The remedy is the internal use of water as fast or faster than it is wasted by the skin, in order to force the kidneys to work and to maintain normal volume in circulation, and the external use of water and sun baths systematically for their toughening and contractile influence on the skin.

Pneumonia; Its Fatality and Increasing Prevalence, with Suggestions for Individual and Communal Prophylaxis.—The conclusions of E. F. Wells are as follows: (1.) The fatality of pneumonia has increased but little, if any, during the past eighty years. (2) The prevalence of pneumonia has steadily increased during the past fifty years, and during the past twenty years this increase has been very great (3) For individual prophylaxis the nasal, pharyngeal, and oral cavities should be kept as free as possible from accumulations of mucus, and when it has been demonstrated that such secretion contains the pneumococcus such efforts should be especially well directed and maintained. In addition, care should be taken not to become chilled when overtired. The individual should, as far as practicable, keep out of range of the extruded pneumococcus-laden secretions of infected individuals. The sputum and other secretions of the respiratory surfaces of pneumonic patients, or of other infected individuals, should be destroyed before it has been allowed to become dry. Such persons should cough and sneeze into a moistened cloth. (4) For communal prophylaxis the information and advice above given should be kept before physicians, with the request that, if they can consistently do so, they give it as their instructions to their patients. (5) There may be some comparatively simple means by which pneumonia may be prevented, but the fundamental information on which prophylactic rules may be formulated is not yet at hand; therefore it should be the province and duty of public health officers to seek assiduously for such knowledge, and he would suggest that, as a preliminary step in this direction, pneumonia be placed on the list of notifiable diseases, and that the environment of pneumonic patients be carefully noted and the results analyzed.

Medical News, November 15, 1902.

Uric Acid in the Blood and Tissues as a Cause for Certain Stomach and Intestinal Troubles.—Freeman F. Ward, in speaking of the presence of uric acid in the body in sufficient quantities to cause disturbance, mentions two factors in the treatment of this condition: The use of the drug, sidonal, and the so-called "Spa Treatment." Sidonal is a synthetical compound of quinic acid and piperazin. Its expense is its only drawback. In those cases in which there was an excess of uric acid in the urine, or a tendency to produce it, this drug worked in an ideal way, but in the cases in which very little or no uric acid was found, after repeated trials, the drug was of no avail, although it did no harm. Mineral waters should be used as carefully as drugs. It is generally conceded that mineral water treatment is contraindicated in acute troubles. But it is efficacious in well-selected cases of chronic disease. It should be recommended only after careful chemical and physical examination. The waters at Saratoga probably offer the greatest variety in their number and strength, in this country. In the course of this treatment there should also be facilities for the proper diet of patients.

Lacerations of the Uterine Cervix and Their Sequelæ.—Charles H. Bushong states that the results obtained from local treatment are always more satisfactory than those from operation. When a perfect cure is made the cervix has absolutely no cicatricial tissue left in it. Such a result is rarely seen after operation In cases of bloody leucorrhœa, attention cannot be paid too early to the case. Energetic, timely treatment will save many from danger. Attention to details is necessary, and each case should be carefully studied for itself. The treatment will require time and patience. Douches should be used and the bowels kept regular. The temperature of the water must be regulated according to the case, but on general principles, hot water is more beneficial than warm water. The writer has found Monsel's solution the most satisfactory drug in promoting the absorption and removal of cicatricial tissue. It is freely applied to the cervix and the surrounding vault of the vagina. The parts over the scar tissue should be flooded with it. The tampon is an important factor in the treatment of these cases. Once a week will be often enough for treatment if the patient is very sensitive. The writer has seen numerous cases benefited by treatment in pregnancy.

Medical Treatment of Cholelithiasis.—R. Alexander Bate gives an outline of the prophylactic treatment: This should embrace preventive measures against the acid dyscrasia; care of the menstruating and pregnant female, especially after the thirty-fifth year; the removal of all things tending to produce stagnation of the bile; the use of all means to promote its fluidity and outflow; the use of agents promoting biliary and intestinal antisepsis, and the use of lecithin or other solvents of cholesterin in those from whom gallstones have been removed. An excess of organic acids must be prevented by increasing oxidation in every way, by out-of-door exercise, bathing, massage, etc., and a diet requiring as little oxygen as possible, and free from calcium salts. Thus no red meats, tea, coffee, chocolate, tomatoes, strawberries, bananas, limestone, or carbonated water should be taken. Lentils are especially valuable, for they not only require less oxygen for their assimilation, but even carry oxygen with them. The oxygenated waters should be used. Eggs, milk, especially buttermilk, whole wheat and corn breads complete the requirements of the diet list. They furnish oxygen, phosphates, and lecithin. Counterirritants—especially salicylate of methyl—and hot or cold enemeta are of some service. The ideal prescription for internal medication would contain lecithin, pichi, and dioscorea. Surgery and medicine are complemental, and should be employed in all cases in which there is any opportunity offered. Combined, they accord a scientific and perfect treatment to cholelithiasis.

New York Medical Journal, November 15, 1902.

Depressed Fracture of the Malar Bone, with Report of Three Cases.—The cases are reported by S. L. McCurdy and photographs of all are given. The author advises for reposition of the depressed fragment a gimlet or an ordinary coat-hook, such as is screwed into closets, etc., which acts ond the gimlet principle, and from the double curve of the handle affords an excellent grasp for the surgeon. In operating, care must be taken to avoid the temporomalar canal on the external surface of the bone. There is also danger of wounding the alveolar branch of the internal maxillary artery with the drill point as it passes through the bone, since this vessel passes forward and downward between the malar bone and the maxilla.

A Case of Ringworm of the Face and Two of the Scalp Contracted from a Microsporon of the Cat, with Some Observations on the Identification of the Source of Infection in Ringworm.—The paper of A. D. Mewborn, the scope of which is sufficiently indicated in the title, is illustrated with eleven well-executed drawings. The attention of parents should be called to the possible danger of infection from the prevalent habit children have of caressing domestic animals. Concerning treatment, Mewborn notes that the resistance of all the parasitic fungi to chemical agents is diminished by the use of an agent removing fat from the scalp and hairs. Hence, ointments having an oily base are not as efficacious as are solutions of the same remedies in alcohol and ether. Valuable agents named are salicylic acid in ether, chloroform, sublimate, carbolic acid, iodine tincture, carbon bisulphide and sulphur dioxide. But in every case epilation must be practised. He concludes by saying that differences of soil modify the clinical picture of skin ringworm as well as the microscopical appearance of the fungus. In the fluid of an herpetic vesicle the mycelium of a microsporon may produce external grape-like spores. Finally the yellowish and brownish bands and the tangential fringe on beer-wort agar can be used to identify the source of infection in ringworm of the cat.

Experimental Investigations with Röntgen Rays upon Living Tissue.—J. Rudis-Jicincky recommends to operators the following rules: (1) Know the capacity of the apparatus, remembering that the so-called *x*-ray burns will be produced with a static machine, just as well as with a coil, and that it makes no difference what apparatus is used. (2) Make a thorough examination of your case to be treated. Know your patient well, observe the corpulence and age, the disposition and resistance, and the complexion also. Remember that an *x*-ray effect on the tissues will be produced, whether the rays are grounded or not, through any substance which is not opaque to the rays, whether aluminum, parraffin wax, or what not. Protect the hair and eyes, and the healthy tissue if necessary, with lead and rubber; the latter to prevent shock by induction. Ray all suspicious parts in as large an area as possible. (3) The length of exposure depends not so much on the time during which the tube is in action as on the actual time of best *x*-ray production, tested occasionally by means of the fluoroscope. Exposure is to be made according to each individual case, for five minutes at first, and after a week, for ten minutes. If, two weeks after the first exposure, no reaction has been shown, the patient is not the subject of any idiosyncrasy, and may be irradiated every second or third day, and finally every day until intense reaction shows itself. During the first exposures the distance of the tube should be six inches, later less than that. If a high vacuum tube is preferred, the exposure must be comparatively shorter. If itching of the skin ensues during the course of treatment a pause of a few days should be made, the parts exposed observed, and a static brush discharge with a wooden electrode given; or, if there should be a peculiar irritability of the nerves or tissues, the skin should be washed with alcohol and warm water. When there is too much sloughing, powder the growth itself with little salicylic acid. In internal growths, however, we expect to get tanning of the skin. (4) If it is thought unwise to treat the whole of the diseased surface at once, begin to to treat the growth, etc., at its edges. If it should happen that one or a few isolated nodules remain after the general surface of the growth begins to look better, a change of treatment is indicated, and the nodules have to be attacked most vigorously. (5) Watch the progress and results of the treatment carefully, and see whether the case is one for operation or not, or whether the raying should be combined with a radical operation before and after. Experience in all these and similar cases is the best guide. (6) Protect yourself, and be prepared for all occasions, having in your office or laboratory a sign, perhaps like this: "*x*-ray examinations and treatments at the risk of the patient. All possible and professional skill used."

American Medicine, November 15, 1902.

The Relation between Pernicious Anæmia and Achylia Gastrica.—Harry Adler presents the following summary: We have to deal, in pernicious anæmia, with a toxic process, the stress of the action of the poison or poisons being exerted upon the blood and cord. The resulting hæmolysis is confined chiefly to the portal area. The gastric atrophy is regarded by almost all authorities as the primary condition. The gastric atrophy presents, then, the conditions favorable for the laboration and absorption of the toxins, the atrophy of the stomach acting, in other words, as a predisposing cause. The writer thinks that we are to look upon the anæmia of pernicious anæmia as but a symptom, but from the marked alteration which the blood undergoes, and the vital effects thereof, it is the most important symptom of the disease to which our therapy for the present must be directed.

An Infectious Form of an Eczematoid Dermatitis.—Martin F. Engman has made a careful study of this condition during a number of years. He calls it "eczematoid dermatitis" because, in the course of the disease, there are papules, vesicles, pustules, and a reddened scaly surface, from which oozes a sticky liquid that stiffens linen and forms crusts. The writer then quotes various cases and finally draws the following conclusions from his investigations: (1) The contents of the initial vesicles, serous, and seropurulent discharge, under surface of crusts and scrapings from freshly-denuded surface of eczematoid skin, produce, when inoculated into artificial culture media, pure cultures of the staphylococcus, yellow or white or both. These cocci sometimes vary slightly in the peculiarity of their growth, but are certainly the staphylococcus of the ordinary types. (2) When the apparently healthy skin of a person suffering from an eczematoid dermatitis is slightly irritated, after being rendered sterile by the usual means, and then inoculated with the discharge from the eczematoid surface, there appears thereon a condition similar in its flora and symptoms to the one from which the discharge was taken. Inoculation experiments from individual to individual have not been encouraging, due most probably to the patient's unwillingness to submit or to the reaction of the foreign soil. (3) Inoculations upon individuals from artificial cultures were also not encouraging. The organism must undergo some change in its chemotactic character in artificial media, as inoculations from it produce impetigo or purely impetiginous lesions, which quickly heal; or if the lesion takes on an eczematoid character it heals too rapidly to be of much experimental value. (4) The suppurative conditions with which eczematoid dermatitis is often associated always contains staphylococci. (5) The association with suppurative conditions; history of apparent infection and auto-infection; the exciting factor of traumatism and infection, with the bacteriologic findings enumerated, all indicate and confirm our belief in the staphylogenetic origin of this dermatitis.

Philadelphia Medical Journal, November 15, 1902.

A Case of Severe Dermatitis Following the Use of Mercurial Ointment.—Lawrence E. Holmes reports this case, which shows a very pronounced susceptibility to the influence of mercury. The patient was a negress twenty-seven years old. There was tenderness of the cervical lymphatic glands following a "sore throat," of some weeks previous. An ointment of equal parts of belladonna and mercurial ointment, to be applied at night by rubbing on the glands, was given. After two applications had been made, the neck became covered with a minute vesicular eruption, which extended down in front over the chest. The area of eruption was dark red, and the tissues were tense and œdematous, and tender on pressure. The face was puffy, and the lips and the eyelids were swollen. There were no constitutional symptoms. There was no salivation. A sedative lotion was given for local use, and a saline purge. The condition improved, and disappeared within a few days.

The Diet in Typhoid Fever.—William Egbert Robertson gives as the difficulties confronting us in the dietetic management of a typhoid case: The exhausting fever, and the state of the bowel. Saliva moistens the food, rinses the mouth dilutes injurious substances, and to some extent neutralizes them. This can be brought about by psychical means alone. If the desire for food can be brought about, and this is more likely when a variety of food is allowed, psychical stimulation will aid in preparing the organs of digestion for the reception of food, and digestion will be more thorough than when merely milk and broths are allowed, for these foods grow very tiresome, and thus psychical stimulation is lacking. As to the bowel lesions, the writer believes that the tendency of the ulceration to slough is favored rather than retarded by the devitalizing influence of insufficient nourishment The writer then gives various statistics, which show that the mortality was less among the well-fed. There was also a striking difference in the physical condition of those discharged. Among the foods allowed by some of those who are not in favor of a liquid diet only are bread, rolls, farinaceous foods, boiled eggs (soft or hard), boiled meat, cutlets, chicken, soups, pudding, jellies, milk, tea, and wine. Although milk is an excellent food, it has a tendency to form curds, and patients often refuse to take it The writer does not advocate a full diet, but he is convinced that typhoid patients can be given a variety of foods without harm and even with decided advantage, both as to their condition during the attack, and as a means of effecting prompt restitution of their physical vigor.

Some Points in the Treatment of Postoperative Abdominal Cases.—John B. Deaver and George P. Müller call attention to the great importance of careful postoperative treatment. If the patient has not been saturated with ether, and if the operation has been performed as quickly as was consistent with thorough work, there is little cause for shock. In fact, shock is seldom seen except in cases of severe hemorrhage. In these cases intravenous transfusion of salt solution may be performed. Atropine, 0.00025, is given every 2 hours; strychnine, 0.001, every hour; whiskey, 2.0, every thirty to sixty minutes, and camphorated oil every fifteen to thirty minutes. Two hundred c.c. of saline solution at 110° F. and 30 to 50 c.c. of whiskey are given per rectum every three to six hours. The time, of course, varies and will depend upon the condition of the patient. In cases of shock in which there is an acute appendiceal abscess with absorption of toxins, the symptoms seldom, if ever, respond to treatment. In clean cases the patient is kept on the back from twelve to forty-eight hours. The time will depend upon the length of the incision. If gauze drainage has been used, the patient is gently turned to one side by pillows at the end of seventy-two hours. In cases with glass drainage, no change is allowed, but the alternate raising of the hips on pillows. In clean cases without drainage, asafœtida suppositories are given every three hours. As a rule, no water is given for eighteen hours or longer if nausea is persistent. In the case of backache, only change of posture, as a rule, affords any relief. The passage of flatus will relieve all colic. If no flatus has been passed at the end of eighteen hours, an enema of milk of asafœtida may be given. On the third or fourth day the bowels are moved with a plain enema, or with a glass of citrate of magnesia. Twenty-four hours after operation nourishment is started, beginning with milk and lime water On the second day chicken broth, beef tea, and junket may be given. On the third, wine-jelly and gruel may be added. Later come soft-boiled eggs, milk toasts, custards, eggnogg, etc. If the temperature persists about 100° in supposedly clean cases to the third or fourth day after movement of the bowels, the wound is examined for stitch abscess. In clean cases the wound is dressed, as a rule, on the eighth day, and the stitches removed. In drainage cases the glass is withdrawn in from two to four days, and rubber is substituted. The latter is shortened daily as the wound granulates Boric acid is used for irrigation in the removal of gauze drainage. In nausea due simply to the ether, the only treatment generally necessary is the prohibition of anything by mouth, the use of rectal alimentation, and a small fly blister on the epigastrium. When nausea develops several days after the operation, it can often be controlled by the administration of a powder like this: Calomel, 0.01; cocaine muriate, 0.015, and cerium oxalate, 0.3. This is followed by a little Vichy, hot water or champagne. In certain cases the only treatment of any avail is lavage of the stomach. This may have to be repeated every few hours for a day or two. It is a very valuable treatment. Purgation is the sheet anchor in the treatment of peritonitis, but is impossible in cases of persistent vomiting. In these cases there is resort to lavage.

The Lancet, November 8, 1902.

Note on Nitrous Oxide Gas, Air, and Chloroform as a Mixture.—The method advised by T. Bird is intended for short operations, and the introduction of pure chloroform in cases in which cerebral unconsciousness is quickly desired A Wolf's bottle, such as is ordinarily used for administering chloroform, is fitted to the tube conveying the "gas" from the cylinder to the bag attached to the ordinary face-piece, the object being to mix as minutely and intimately as possible the nitrous oxide gas, the air, and the chloroform. An expiratory valve is the only one ever used, and that is incomplete [illegible]

Tape Worms as a Possible Cause of Diabetes.—J. E. Judson reports two cases in which tape worms were found associated with glycosuria In one case it was impossible to dislodge the head of the worm, and the patient went through the usual diabetic course Autopsy revealed a liver enlarged and with a tendency to cirrhosis. The lungs were tuberculous and the pancreas apparently normal, though no microscopical examination was made. Case 2 had gangrene of the big toe and was not followed to its termination Judson suggests the theory that the head of the tape-worm might very possibly get into the pancreatic duct and become well fixed to the wall by means of its hooklets, and through the inflammatory change which it would produce would cause an occlusion of that duct. We know that extirpation of the pancreas brings on glycosuria in animals, owing to the absence of the internal secretion, the presence of which is necessary in order that the normal assimilative processes can take place with the glycogen. If the duct be occluded, no doubt the gland will in time atrophy, and so become useless. This would then exhibit the same condition as if it had been extirpated.

Case of a Large Dermoid Cyst Complicating Labor.—The patient of B. J. Macaulay was a primipara of twenty-seven years. Labor progressed so slowly that it was decided to apply the forceps. The instrument was easily applied, but the head would not move. On releasing the traction momentarily, without any warning, there appeared extruded from the vulva a cyst rather larger than the fetal head and attached by a long pedicle. A catheter was passed and the urine was drawn off, but the swelling did not diminish and a pedicle could be felt attached. As there were prolapse of the funis and some hemorrhage, the question of placenta prævia was entertained, but the insertion of the cord could not be felt, and the tumor was too cystic. After consultation it was decided to remove the forceps and to puncture the cyst. This was done, and a thick, green, pultaceous material was extruded. An incision was now made and a large quantity of matted hair was removed. The empty cyst with its long pedicle was brought down and retained outside the vulva by means of a ligature. The forceps was again introduced and the child was easily delivered (dead) with the placenta which followed a few minutes later. The pedicle of the cyst was found coming through a rent in the left side of the cervix. The fetal head had during traction with the forceps forced the cyst from within the peritoneal cavity through the cervical wall. Owing to the extreme collapse of the patient, it was not thought advisable to anæsthetize and sew up the rent, but to bring the pedicle through the rent, and trust to formation of adhesions. Patient died on the sixth day from peritonitis. No autopsy was held.

British Medical Journal, November 8, 1902.

The Bradshaw Lecture on Intraperitoneal Hemorrhage Incident to Ectopic Gestation.—Charles J. Cullingworth enumerates the following points upon which he chiefly depends in diagnosing this condition: (1) The fact that at the moment of the attack the patient was in her usual health. This circumstance would render it highly improbable that the symptoms were due to gastric or intestinal perforation, or to rupture of an internal abscess or suppurating cyst. (2) The gradually increasing pallor of the patient, and the gradually rising pulse rate (without corresponding rise of temperature), both being indicative of internal hemorrhage. (3) The extreme tenderness of the abdomen. To this symptom the writer has learned to attach a very special value. It often misleads the medical attendant into supposing that there is acute general peritonitis. It cannot, therefore, be too strongly insisted upon that marked, and even excessive abdominal tenderness, does not necessarily indicate an inflammatory condition. It is met with, for instance, over ovarian tumors when, as the result of rotation of the pedicle, they have become the seat of hemorrhages, intracystic and intramural. It is quite true that peritonitis is a not infrequent later result of this accident; but this marked tenderness may be observed when, on opening the abdomen, there is no visible sign of inflammation. (4) If a menstrual period has been missed or is overdue the diagnosis of the case is greatly facilitated, but it does not follow that because menstruation has been regular rupture of an ectopic gestation may be excluded. For some of the most appallingly sudden cases of rupture occur at a very early stage of the pregnancy, even, it may be, before a single period has been missed. Hence arrested menstruation is not essential to the diagnosis, though when present it is a valuable help to it. If, in addition to the arrested or delayed menstruation, there is morning sickness, the diagnosis is even further facilitated. But, after all, these signs of early pregnancy do not prove very much. They do not even prove that the pregnancy, if present, is ectopic, or that, whether it is or not, it has anything to do with causing the present illness. All that can be said is that when symptoms are present that suggest the possibility of a ruptured ectopic gestation, these signs of pregnancy serve to confirm the suspicion. The signs obtained by vaginal examination are not very definite In these cases of diffuse intraabdominal hemorrhage there is absolute necessity for prompt surgical treatment. Probably a large majority of cases of pelvic hæmatocele are due to ectopic gestation. Pelvic hæmatocele is generally characterized by irregular uterine hemorrhage, and by attacks of pain, more or less severe; these are often accompanied by vomiting, followed by the development of a definitely circumscribed swelling. This may be found on the affected side only in the region or the uterine appendages, or it may more or less fill up the posterior pelvic cavity, and rise to the lower part of the abdominal cavity. In differentiating between pelvic hæmatocele and an ovarian cyst with intracystic hemorrhage from twisted pedicle, the writer suggests two points: An ovarian tumor is seldom as closely connected with the uterus as a tubal pregnancy would be. In twisting of the pedicle, a tumor can be found at once, and can be observed quickly to increase in size; in tubal gestation with hæmatocele a tangible tumor is not formed at once. It is generally several days after the onset before any swelling can be made out. Concerning the etiology of the conditions treated in this paper, the writer states that it has been observed that the ordinary result of tubal rupture is a diffuse and highly dangerous intraperitoneal hemorrhage, while the ordinary result of bleeding from the open mouth of the tube is the formation of a hæmatocele. As to the outcome of pelvic hæmatocele or of a diffuse but non-fatal intraperitoneal hemorrhage, the tendency in both cases is to the gradual absorption of the extravasated blood and to the recovery of the patient. But there are dangers to be considered, and of these the two most important are the liability to fresh hemorrhages and the liability to bacterial infection of the blood already poured out. The writer concludes by saying that gynecology is becoming more surgical, but that is all the more reason why medicine should still keep a hold upon it, to exercise a wholesome restraint upon its surgical enthusiasm and to continue to inspire it with that reverence for accuracy of diagnosis which otherwise it might be apt to lose.

Deutsche medicinische Wochenschrift, October 23, 1902.

Significance of the Meconium Plug in the New-Born.—Hugo Weil thinks that the absence of a typical meconium plug in the new-born is of no significance in determining whether intra- or extrauterine death took place. This is based upon the fact that of 500 births observed by the author in only one was a typical meconium plug found after birth. On the other hand, if in a dead-born child a typical meconium plug is present it is very strong evidence that the death was extra- and not intrauterine, since, in the latter event, it is practically certain that after the death of the fœtus, and before its expulsion from the uterus, the meconium plug would be dislodged.

Palpation of the Pylorus.—W. P. Obrastzon reports nine cases in which it was possible to successfully palpate the pylorus. This, of course, can only be accomplished in those cases in which the pylorus is placed at a lower level than the left lobe of the liver. In instances in which it can be felt the pylorus appears to be of a cylindrical form, running transversely across the epigastrium from 2 to 7 cm. above the navel. The peristaltic motion of the organ may be plainly felt, and in many cases slight murmur heard upon auscultation. Very often spastic contractions of the pylorus may be detected upon palpation. It is doubtful, however, whether such contractions have a definite pathological significance, and, in all probability, they occur in a number of different abnormal conditions. Palpation of the pylorus should not be confounded with that of the transverse colon. It can be easily differentiated therefrom by the fact that in the former the cylindrical form felt always lies above the lower border of the stomach. The chief use of this procedure is the differentiation between real and apparent tumors of the pylorus. The rhythmical occurrence of the spastic contractions renders the latter diagnosis certain.

Berliner klinische Wochenschrift, October 27, 1902.

Hæmolysis in Heterogeneous Serum.—P. Baumgarten' after continued studies relative to this subject, still maintains his original views with respect to the osmotic nature of the process and the identity of the agglutinins and antibodies. Baumgarten has never held that hæmolysis is entirely an osmotic process, but that it is essentially such, the osmosis being favored by the action of the specific antibody. The author, as is well known, founds his view of the essential osmotic character of hæmolysis upon the direct microscopical observation of the process, which shows morphological differences between it and the osmotic changes occurring in red blood cells when placed in anisotonic salt solutions. This view is not in any way antagonistic to the essential features of Ehrlich's theory. In fact, when viewed in the proper light, the only difference between Ehrlich and Baumgarten relates to the mode of action of the antibody. Ehrlich asserts that its action is that of a ferment upon the hæmoglobin, while Baumgarten denies any fermentative action, and says that the antibody merely makes the hæmoglobin more susceptible to osmotic influences. The latter thought at first that the action of the antibody was directed entirely toward the plasma, making it marked anisotonic for the erythrocytes. Further researches, however, have shown that such is not the case, but that the antibody exerts its action mainly, if not entirely, upon the hæmoglobin. Recently considerable discussion has taken place between the identity of the agglutinins and antibodies. Baumgarten takes the affirmative side of this question and regards it as certain that the agglutinins and amboceptors are identical, and as very probable that this also applies to the agglutinins and immune bodies (amboceptors + complements).

Streptococci and Antistreptococcus Serum.—Hans Aronson adds further knowledge along this line by the detailed study of streptococci obtained from various sources, such as scarlatinal, diphthtertic, and follicular anginas, the blood of scarlatinal and rheumatic patients and those suffering from general septicæmia, from phthisical sputum, and from the lymphatic glands of sick horses. Streptococci obtained from these various sources show no characteristic morphological or biological characteristics, and any slight differences in these respects which may be present at the time of their isolation quickly disappear as the result of artificial cultivation, so that after one or two generations the streptoccoci from the various sources cannot be differentiated on morphology or culture characteristics one from the other. Aronson's chief aim was to evolve an efficient antistreptococcus serum. To this end it was necessary that the streptococci should be made as virulent as possible. Great difficulty was at first experienced in this task. Finally it was accomplished by inoculating rabbits at the same time with large doses of the streptococci bouillon cultures and small doses of diphtheria toxin. Animals thus treated die in three or four days, and streptococci obtained from their heart's blood are very virulent for other rabbits, regularly killing them without the aid of the diphtheria toxin. The same result was obtained by inoculating mice with the streptococci. These animals shortly died, and the streptococci obtained from their blood were very much increased in virulence, so that they regularly, upon inoculation into rabbits, killed these animals in from three to four days. The next task was to make an artificial culture medium in which these virulent organisms could be cultivated and preserved without a deterioration in their virulence. For this purpose a bouillon made from horse meat and containing .5 per cent. salt, .5 per cent. peptone, and .1 per cent. glucose was found the most suitable. In order to assure good results, it is very important that this medium should react alkaline to litmus, but neutral to phenolphthalein. In all the endeavors to obtain an antiserum by animal inoculation the streptococci used were increased in virulence by one of the two methods above noted, and inoculated in the form of this horse-bouillon culture. Although in this manner, as above stated, the streptococci could be markedly increased in virulence, it was not found possible to obtain from such, in artificial culture, any large amount of toxin, so that no very marked immunity could be produced in animals by the inoculation of such culture filtrates. If, however, small animals (rabbits) were repeatedly treated with such culture filtrates, it was found that they, upon inoculation with virulent streptococci, lived somewhat longer than animals which had not been thus previously treated, and it seems possible that improved methods may render possible the immunization of rabbits to highly virulent streptococci by the previous inoculation of toxins. Horses were used in the production of an antistreptococcus serum. These animals were inoculated with the virulent streptococci cultures above described. Different horses were immunized, obtained from the various sources above mentioned. The sera thus obtained were tested upon rabbits, when it was found they protected these animals not only against the streptococci with which they were produced, but also against streptococci of other origins; thus a serum obtained from the inoculation of scarlatinal streptococci protected rabbits not only against such streptococci, but also against diphtheritic, rheumatic, tuberculous, etc., streptococci. Such sera also gave interagglutination and precipitin reactions. These facts are very strong evidence in favor of the unity of the streptococci, and are directly opposed to the views of Marmorek, who regards them as a multiple species.

Münchener medicinische Wochenschrift, October 28, 1902.

Ovariotomy During Pregnancy.—M. Graefe says that ovariotomy should be done during pregnancy as soon as a diagnosis of ovarian tumor is established. To support this contention three cases are reported which came under Graefe's personal observation, together with twenty-four which have been reported by various authors since Orgler published his 146 cases. In these twenty-seven cases there was no maternal mortality, and only in six did miscarriage or abortion take place. If these are added to Orgler's cases, the maternal mortality is reduced to 2.3 per cent. and the fetal to 16 per cent. [illegible] therefore, that on the ground of maternal mortality an ovariotomy during pregnancy is not contraindicated. The fetal mortality, while reasonably high, cannot be advanced as a valid objection to an early operation, since it is certain that it would be increased by delaying the operative procedures and allowing the tumor continued growth. It goes without saying that the operation should be conducted with all possible haste, and all manipulation of the uterus restricted so far as possible.

French and Italian Journals.

Stercoraceous Vomiting of Hysterical Origin.—Ferdinando Fazio reports a case, and reaches the following conclusions from a study of the subject: Stercoraceous vomiting may be of purely hysterical origin. It cannot be due to simple antiperistalsis, and there must, therefore, be some morbid and mechanical obstacle; this may be a state of spasm or of paralysis. Spasm is more apt to occur in the cases of rapid onset, without preexisting constipation, and paralysis in the slow cases with constipation. Treatment should be of a psychical suggestive nature.—*La Riforma Medica*, October 29, 1902.

Treatment of Rheumatic, Simple Infectious Endocarditis.—Henri Huchard declares that salicylate of soda ought to be prescribed in large doses from the beginning of rheumatism, especially in children, and be continued even after the complete disappearance of the articular troubles. He does not believe that this medication possesses a direct action on the inflammatory process of endocarditis; it does not cure it, it prevents it, which is still better. The inflammation of endocarditis is a phenomenon of reaction. Although salicylate of soda is a specific antirheumatic, it also possessses an action over the microorganisms of rheumatism, and this fact explains its good effects when it is employed early.—*Journal des Praticiens*, October 11, 1902.

Affection of the Stomach Simulating Cancer.—M. E. Klein reports the case of a man of forty-two years who had suffered for about six months with his stomach. The family and personal history were negative. The trouble began with pain and vomiting. The pain came on in irregular paroxysms which were not modified by eating. Finally, he vomited dark blood about an hour and a half after eating. After that the stools were also often black and liquid. He could eat bouillon, milk, and eggs. He became emaciated and weak, although he continued his work. He looked yellow and cachetic. The liver was not painful. The urine was negative. There were no physical signs of tumor. A milk diet was ordered, and the patient gained in weight and strength till he attained perfect health. The trouble was probably an ulcerous lesion.—*Journal des Sciences Médicales de Lille*, October 11, 1902.

A Case of Postdiptheritic Paralysis of Accommodation and Convergence.—Etienne Ginestous reports this case. The patient was a little girl of nine years. She was treated with antidiphtheritic serum. When she left the hospital her palate was paralyzed, and her sight was poor. The illness occurred in March of 1900, and the paralysis of accommodation has persisted ever since, that is about two years. This differs from the classic descriptions which assign to postdiphtheritic paralysis a rapid evolution and a short duration. In this patient also the paralysis of accommodation seemed to be the last vestige of a diphtheritic infection. The muscles of accommodation and convergence were the last ones affected. This is an interesting fact in comparison with other cases reported.—*Gazette Hebdomadaire des Sciences Médicales*, October 12, 1902.

Asphyxia from Carbonic Oxide.—J. Noir states that the symptoms of intoxication by this gas are characteristic. When there is extreme intoxication, death comes quickly, sometimes with convulsions. In gradual intoxication, the victim suffers first with violent headache, with constriction of the temples, then with vertigo, troubles of vision, shiverings, hallucinations, and a desire for sleep. Then follows a stage of helplessness. There is often vomiting at this time, and sometimes relaxation of the sphincters. Only after all of these disturbances comes the loss of consciousness and coma. If the individual is revived, there is found to be temporary glycosuria. Complications such as pneumonia may occur. There have been noted the development of skin lesions. Also many nervous troubles have been observed, even paralysis. The treatment consists in giving oxygen to the red blood-corpuscles. Artificial respiration should be practised to provoke pulmonary ventilation. Various other methods are in vogue, such as the transfusion of blood.—*La Progrès Médical*, Ocober 11, 1902.

Society Reports.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held October 20, 1902.

Alexander Lambert, M.D., President.

Dr. Parker Syms, on retiring from the office of President, expressed his hearty thanks for the coöperation of the members, and complimented them upon the great progress made during the past two years. Much, he said, had been accomplished not only in a scientific way, but in regulating the practice of medicine in this city, and in elevating the profession. It was also a cause for congratulation that the committee on ethics and discipline had had practically nothing to do. He then introduced his successor, Dr. Alexander Lambert.

President's Inaugural Address: "The Present Ideas of Immunity."—Dr. Alexander Lambert delivered this address. The subject was divided into natural and acquired immunity, and this subdivided into the resistance to bacteria themselves, and the resistance to the bacterial poisons or toxins—in other words, into bacterial immunity and antitoxic immunity. There were two principal theories, he said, regarding immunity, viz., (1) The phagocytic theory of Metchnikoff, and (2) the old humoral theory. The latter had been brought down to a common ground with the phagocytic theory. In studying natural immunity, experiments showed that the serum of an animal immune to a certain bacterium was an excellent culture medium for that bacterium; hence, some mechanism in the body besides its juices was the dominant factor in preventing germ invasion. In animals naturally immune against infection the symptoms of heat and swelling, and the symptoms produced by the injection of bacteria were small in amount, but a strikingly large number of leucocytes were attracted to the point of invasion, and the chemotaxic power of the leucocytes was marked. The most striking examples of immunity against toxins were to be found in the hen against tetanus, and in the rat against diphtheria. The rabbit would bear 30 grams of morphine hydrochlorate subcutaneously, but would die from a milligramme of the same injected into the brain. It had been shown in typhoid and cholera that animals immunized by the bodies of the bacteria would succumb to the poisons of these same germs. The chemical bond between the toxin and the antitoxin did not seem to be strong. Mixtures of bacterial toxins and their antitoxins when forced through filters of thin layers of gelatin showed separation of the two components, and the toxins alone appeared in the filtrate. At first the agglutinating and immune substances were thought to be one and the same, but it had since been proved that they were distinct and separate, and that agglutination was the action of infection as well as of immunity. Experiments seemed to show that certain sensitive bacteria, such as those of cholera, were disintegrated, and then absorbed, but this was by no means the general rule. The subject of agglutination was still a question open for discussion. Certain animal serums normally agglutinate certain bacteria and heterogeneous blood. The outside envelope of the bacteria had been found to be the portion containing the agglutinating substance The various theories regarding agglutination were then presented and briefly discussed. The speaker said that the study of precipitins in the blood bade fair to assume great medicolegal interest, especially as the tests were applicable to dried blood stains. However, the reactions were claimed by Nuttall not to be absolutely characteristic. For example, human blood caused cloudiness in the blood of baboons and monkeys, although this partial reaction would not be mistaken for that which would be given by homologous blood.

THE NEW YORK ACADEMY OF MEDICINE.

Section on Medicine.

James K. Crook, M.D., Chairman.

Stated Meeting, Held October 21, 1902.

Symposium on Typhoid Fever.—This was the special subject for the evening.

The Etiology and Prevention.—Dr. Herman M. Biggs read this paper, confining himself chiefly to the disease as it occurred in the Borough of Manhattan. Investigation of the source of the disease was attended with great difficulty and unsatisfactory results, but in New York it was assumed that the water supply was not the source of infection, because of the fact that the general condition of the Croton water-shed was good; that if it was contaminated it would be so relatively slight as to give a very low morbidity or mortality rate from the diffusion. In New York City when a case of this disease was reported an inspector from the Board of Health was sent to the patient and endeavored to learn if the patient had been out of the city, where, and for how long a time; if he had eaten oysters; if he had been accustomed to drinking milk; if he had been in contact with any typhoid-fever patient. Although it had been very difficult to obtain information, still it was found that in from 20 to 30 per cent. of the cases occurring here there could be obtained no definite history of the disease having been contracted out of the city, and that in about 5 per cent. the infection was the result of direct transmission. It was found to be almost impossible to determine the possibility of infection through the ingestion of oysters, except in certain instances. Milk from a dozen or more farms is thrown into a single vat, which made it difficult to trace the source of infection from milk. Bathing in the North or East rivers had been learned to be a source of the disease on account of the proximity of the large sewers. During the past summer the Department of Health would not allow baths at certain points in the river. The speaker related four instances of local outbreaks in which the possible source of infection cast considerable light upon the probable source of infection as it might occur in New York City. With regard to the prevention, two measures, which the Department of Health had under consideration, were: (1) Devising some means to regulate the sale of oysters, and to determine their source; the custom of feeding and fattening oysters on brackish water was dangerous; (2) Devising some means for closely supervising the milk supply to the city.

The Symptomatology and Clinical Diagnosis.—Dr. Charles E. Nammack read this paper, and divided his cases into the following groups: (1) The ordinary typhoid fever with marked enteric lesions. (2) Typhoid septicæmia, a general infection without special local manifestations. (3) Typhoid fever, with marked localized symptoms other than those of clinical typhoid fever; these cases will be masked by the predominance of symptoms referable to the kidneys, spleen, etc. (4) Mixed infection. He thought that the consideration of the source of the infection other than from the water supply was timely. The rash he believed to be the most valuable single sign, and with an enlarged spleen and the fever made a triad of symptoms which were of great diagnostic importance. The absence of leucocytosis in a suspected case was of value. During the first week of typhoid fever it was oftentimes difficult to make a dignosis between typhoid fever, cerebrospinal fever, and miliary tuberculosis. Other diseases with which it might be confused were the exanthems, influenza, tuberculous peritonitis, ulcerative endocarditis, and secondary syphilis.

Laboratory Aids in the Diagnosis of Typhoid Fever.—Dr. E. E. Smith read this paper. He said there were three purposes which corresponding laboratory tests have in view: (1) The detection of characteristic morbid products of the disease; (2) The isolation and identification of the infecting organism, (3) The detection of certain cell products, the agglutinins, or one of the constituents, the presence of which is induced by the infecting organism. The detection of morbid products more or less characteristic of the disease is practically limited to the test for the unidentified substance which gives the diazo-reaction of Ehrlich. Its value was variously estimated by different observers—those of the New York Health Department being most favorable. This opinion was, perhaps, tentative, since it was not based upon the result of the public use of the test. Observers going to the other extreme placed very little value on the test. It was probable that the conclusions of different observers regarding its value were influenced to some degree by the standards adopted as to what constituted a positive reaction. Then, again, the test should only be made with urine to which preservative has not been added. The speaker believed that the test was of sufficient value to warrant its routine use, but that its occurrence was distinctly less frequent than in 90 per cent. of all typhoids from the third to the sixth day, and that it may be present in tuberculosis, scarlet fever, pneumonia, malaria, measles, erysipelas, general carcinosis, and paratyphoid, as found by various observers. It was to be treated as one bit of evidence in conjunction with other symptoms. The isolation of the infecting organism is of clinical value only when it can be expeditiously accomplished. One accustomed to the examination was now enabled, by the use of special media, to accomplish this, in many cases, in from forty-eight to seventy-two hours. A positive result he considered to be pathognomic. Objections to the examination of the rose spots were the uncertainty of the appearance and identification of the eruption, and the absence of the bacilli in some true typhoid spots; also, the inconvenience in private practice of taking the specimen. In many cases, too, the organism was not found in the urine and fæces, but the readiness with which these cases can be obtained rendered their examination worthy of more extended application. Regarding the Widal test, this reaction, in the hands of a competent observer, must now be given great weight in establishing the diagnosis. It was in the absence of a positive reaction that clinicians found the greatest defect in this laboratory aid. The absence of the blood findings assisted in excluding other causes of fever, although their existence did not necessarily exclude typhoid fever, though rendering it much less probable. The agglutination reactions with the intermediate bacteria, the paratyphoids and paracolons, aided in establishing the diagnosis in a small percentage of cases, though not in the typhoids with delayed Widal reaction. The conclusion was reached that, while the laboratory did not offer any one test that was certain at all times and in all cases, it did materially aid the clinician by the means mentioned, at times strengthening an early suspicion in cases that later presented the classical symptoms, and, in some instances, identifying atypical cases that, without its aid, would have escaped recognition.

The Chemical Nature of Bacillus Typhosus.—Dr. Lewis R. Morris stated that chemical studies of bacteria had hitherto been directed chiefly to the products formed by the life processes of bacteria. Believing that the chemical nature of the organisms themselves should be studied, he began, with Dr E. E Smith, over a year ago to collect and study the chemical nature of the bacillus typhosus. As it took a long time to raise and collect enough bacilli to form sufficient material for chemical analysis, the process was slow and tedious Dr. Morris presented on the blackboard a comparison of analyses on bacillus tuberculosis, bacillus malleus grown in broth, and of bacillus typhosus grown in broth and glycerin agar. They found that the bacillus typhosus was not rich in sulphur and phosphorus-containing bodies in comparison with the bacillus malleus. They also found that the same increase of contents of nitrogenous substance occurred in typhoid-fever organism grown in glycerin medium as had been found in tubercle bacilli grown in the presence of glycerin He raised the question whether this may be because the glycerin added to the medium caused a much more luxuriant growth of the bacteria, and so promoted the production of nitrogenous substance in these lower forms of life

The Treatment of Typhoid Fever.—Dr Hobart A. Hare of Philadelphia read this paper He did not know of one malady which better illustrated the axiom *nil nocere*, than this disease, and he would be glad to know of any other disease in which the physician more commonly poured "drugs of which he knew little into a body of which he knew less." He asked if it would not be a good motto if, in every case of typhoid fever, the bed was labelled "let the patient get well." He did not wish to be thought a nihilist as to treatment of typhoid fever; on the contrary, he was convinced that there was no disease in which the skilful use of remedies was so needful for the relief of annoying symptoms, the removal of dangerous complications, and the maintenance of normal functions. Upon the kidneys fell the duty of eliminating the toxins of the disease itself, the toxins of other infecting organisms, and the waste products of the fever; for the maintenance of this function, pure water was to be insisted upon, given frequently and in small quantities, and, if need be, aided by mild refrigerant diuretics.

Intestinal Antisepsis.—The subject of renal excretion was closely related to intestinal antisepsis, about which there was so much difference of opinion. It was closely related because nearly all the chemical intestinal antiseptics were largely eliminated by the kidneys, upon which were thrown increased labor and, perhaps, irritation; he believed this to be the chief argument against the use of these preparations as a class, for they might do harm. The use of intestinal antiseptics should neither be largely relied upon nor ignored. If a drug used for this purpose was surely harmless, if its use seemed to diminish tympanites and fecal fetor, it served a useful purpose as an aid, but no one should think that it could have any effect in aborting or curing the affection *per se*. A new substance called acetozone had been found to render the stools of rabbits receiving it entirely sterile, and he hoped that this might prove a valuable agent to modify some of the annoying symptoms and possible complications of the malady. That intestinal antisepsis was a curative agent, very few of its ardent advocates would claim.

Antipyretics and the Cold Bath.—Dr. Hare believed that antipyretic drugs should rarely, if ever, be used in enteric fever. An antipyretic drug he considered utterly unfit for use with the cold bath. The dominant influences of the latter were to equalize the capillary circulation, to redistribute the stagnant blood, to counteract the depressing influences of poisons on the nervous system, to increase the elimination of these poisons, and to bring about their rapid destruction by increased vital activities of the body All of these influences the antipyretic coal-tar drugs prevented. In other words, they prevented that *sine qua non* of the cold bath in health and disease, namely, reaction In the majority of cases, he found that cold rubbing was far better than the cold plunge.

Modified Cold or Hot Baths.—Not only did Dr Hare believe that in the modified cold bath we had the best measure of benefiting our patients, but that very extraordinary modifications of it might be advisable extending from actual hot water to the direct application of ice to the patient; for, if it was true that the chief effect of cold bathing was the production of reaction, then it was conceivable that conditions might exist in which a reaction produced by the use of heat would be better than one caused by cold After many thousand warm baths, Hirschfeld concluded as follows. (1) The average fall of temperature obtained through these baths was 1.5° to 2° F.; (2) In the large number of cases a bath of 85° will bring about a greater reduction than one of 80° of the same duration; (3) In a small number of the patients (principally the aged, weak, and children) a bath of 90° is more effectual than one of 85°; (4) There are a few cases that offer considerable resistance to refrigeration through tepid baths. From the result of experiments, Hirschfeld concluded that: (*a*) The first reason which may be assigned for this apparently paradoxical fact, that tepid baths will bring about a greater reduction in temperature than a cooler one, was that the patient did not part with his heat so readily in the cold as in the tepid bath, because the initial contraction of the blood vessels in the skin in the cold bath allows less blood to pass through the skin, and, consequently, less heat was dissipated. (*b*) The colder the water the more frequently shivering followed the bath. Shivering raised the temperature of the body rapidly through lessening the circulation of the skin and through the involuntary action of the muscles, in consequence of which less heat was being produced. (*c*) The temperature of the body was the result of two factors, the production and the dissipation of heat. It was an undoubted fact that the cold bath stimulates the production more than a warmer bath. Dr. Hare did not think that this subject of baths had received the attention it deserved.

Use of Drugs.—Dr. Hare regarded turpentine as of great value when the tongue was dry and coated and the belly tympanitic. Aside from the favorable effects of the bath, he believed that alcohol was the stimulant *par excellence* in this disease, and that cold over the præcordium was a valuable means of slowing a too rapid heart. He believed that the use of strychnine was often detrimental to the patients. It had always seemed to him that strychnine was essentially an irritant stimulant, which should be applied in a crisis, only a few doses at the most being given, and that its continued employment was like applying a whip constantly to a tired horse, with the result that, in the end, less energy was developed.

Diet.—Most cases of typhoid fever needed not milk alone, but easily-digested starchy foods, or foods of this type helped in the digestive process by appropriate remedies. He also allowed two eggs a day, soft boiled.

Hemorrhage from the Intestines.—Dr. Hare had never heard of any remedy which appealed to him as part of rational therapy in the treatment of this complication unless it was calcium chloride or gelatin. Application of the ice-bag he considered to have little or no effect, and it often deprived the patient, already shocked and anæmic, of vital heat. When a hemorrhage was really active, no drug which acted as a styptic could get to the bleeding spot soon enough to effect a good result.

Mortality Rate.—Dr. Wm. H. Thomson did not think the death rate from typhoid fever should exceed 2 per cent. During the past few days, at his request, the house staff at Roosevelt Hospital had gone over the list of deaths which occurred in that institution from June 1, 1901, to October 11, 1902. The death rate occurring in patients who had been received in hospitals could not be compared to the death rate of patients elsewhere; sometimes these patients were received in the second, third, or fourth week of the disease, and even at the point of death; therefore he drew the line at the fifth day, because he did not believe that any amount of hospital treatment could be considered as effective unless the patients were under care for more than five days. During this time, in the medical wards, he treated 108 patients with eight deaths; of these eight deaths, five could not be included, for reasons given.

Treatment.—Dr. Thomson believed in stimulating the kidneys from the beginning, and, for this purpose, he used rectal irrigations of salt solution. Intestinal antisepsis should be borne in mind from the beginning to the end. He employed calomel, 5 grains; compound jalap powder, 35 grains, every night until the fifteenth day. Bismuth, in 10 to 30 grains, was employed as the only intestinal antiseptic, and this was repeated every three hours. As a diet, he employed milk and lime water, half-and-half, until the third week, when gruel was admitted, with pepsin in in 10-grain doses every three hours. The cold baths were employed whenever the temperature was 103° or over, and he never allowed a patient to have a temperature beyond that point. The cold bath greatly increased elimination by the kidneys; the toxicity of the urine has been shown to be doubled by a cold bath within two hours after its administration. The death rate should not exceed 1 or 2 per cent.

Dr. R. Van Santvoord got along without the tub bath, relying chiefly upon sponging. He referred to the difficulties attending the use of the cold bath in private practice. He spoke of the first patient he had seen troubled with cold baths while he was an interne at Bellevue Hospital. The bath was given under the direction of Dr. Welsh. When the patient was removed from the cold bath he said "Dr. Welsh was not fit to be a savage." He deprecated the cold bath on account of its severity.

Dr. Andrew H. Smith said that the elevation of temperature in these cases was from three sources, viz., (1) the typhoid infection, (2) absorption of putrefactive food, (3) constipation. During the third week of the disease there were numerous points in the intestines through which infection might take place, such as may occur in any open wound.

Dr. A. Jacobi said, with regard to the use of strychnine as a cardiac stimulant in typhoid fever, that, if given in small doses, there would be no influence; if given in large doses, it would be injurious. In every case of myocarditis, it was not the whole heart that was degenerated, but only localized spots in it; these were more or less normal and abnormal tissues. If strychnine acted upon the whole heart, it must act differently on the healthy and diseased parts. When strychnine was given in a case of chronic myocardium degeneration, the pulse became more irregular; when it was left off, the heart became more regular. Strychnine should not be used indiscriminately as a cardiac stimulant. He usually gave one dose of calomel at the commencement of the disease. He was afraid to give it toward the end of the first or second week, because most of the hemorrhages occurred during that time, the majority of them occurring on the ninth day, at a time when the scurf of the ulceration will fall off. Every purgative administered at that time increased the possibility of hemorrhage. Rectal injections were good for many things; for the purpose of relieving constipation, which was so frequent in this disease; for the purpose of relieving diarrhœa; for the purpose of relieving not only the diarrhœa, but the fetid diarrhœa. For this latter purpose he employed thymol, 1-3,000. He never fed his patients on solid food during the course of this disease, although he was aware that well-known clinical teachers said that solid food should be given. The diet should be fluid in character, such as milk, mixed with lime, barley, or rice water. Milk was made more digestible by the addition of cereals.

Dr. James K. Crook did not think that sufficient attention was paid to the disinfection of the urine. Unless properly disinfected, the urine was capable of transmitting the infection for one year after convalescence.

Scarlet Fever Arising after Operations on the Throat.—J. W. Washbourn records seven cases in which, after operations for adenoids, enlarged tonsils, cleft palate, and turbinal enlargements, etc., a typical scarlet rash supervened, followed by desquamation. It may have been that the operator introduced the scarlet-fever virus on his instruments or fingers, or that the virus was present in the throat at the time of operation. While we do not know the exact cause of scarlet fever, it may be that it is present in the mouth more or less of the time, just as is the diphtheria germ, ready to effect an entrance through any solution of continuity.—*Clinical Journal.*

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Annual Meeting, Held October 27, 1902.

Frank Van Fleet, M.D., President.

This being the annual meeting, most of the session was devoted to routine business and receiving the reports of standing committees. The report of most general interest was that of the Milk Commission.

Report of the Milk Commission.—Dr. Rowland G Freeman presented this report. He said that since the reorganization of the commission eleven months ago the scope of its work had been considerably enlarged, and the commission was now on a self-supporting basis. The duties of the individual members had not been permitted to become very onerous, and this division of labor had given very satisfactory results. There were two grades of milk produced under the supervision of the commission, viz.: (1) The higher grade, called "certified milk"; (2) That grade designated as "inspected milk." While the latter must be produced in a cleanly and scientific manner, the commissioner refrains from imposing upon the producer any expensive conditions which are not considered to be absolutely necessary. For the production of the first grade, or certified milk, the barn-yards must be kept clean and free from smell and moderately free from flies during the summer. The stable must be clean and well ventilated, and as free as possible from dust, and the manure must be removed daily. Of course, the water supply must be pure. The cows are examined by a skilled veterinarian, to exclude tuberculosis and other diseases, and the animals are not fed on such things as would impart a disagreeable flavor to the milk. The animals are groomed daily, the long hair near the udders being clipped, and the udders are washed or wiped with a damp cloth before each milking. Wet milking is forbidden, and the milkers are required to wear washable overalls during milking, and they must not be sick or have been exposed to contagious disease. As a further precaution against contamination, young children, as well as cats and dogs, are excluded from the milking place, and the first milk expressed from the teats is discarded. The dairy building must be separate from the house, the utensils must be thoroughly sterilized, and the milk must be rapidly cooled to below 45° F. The bottles of milk are stopped with pasteboard disks and covered with metal caps, though in the near future it is intended to substitute a sealed tin cap. In addition to all these precautions, the milk must be examined at the laboratory every week, and it is subject to examination at any time. The average bacterial content must be less than 30,000. The farms are inspected at intervals. This certified milk is sold by the dealers at prices verying from ten to twelve cents per quart. The inspected or second-grade milk must have 4 per cent. of butter fat, and must not have an average bacterial content exceeding 100,000 in summer, and 60,000 in winter. In general, the care of the dairy and the cows and the precautions in milking are the same as for certified milk. These farms are inspected, and the milk examined at the laboratory, once a month. This milk usually sells for eight cents per quart, the usual price of milk produced without sanitary supervision. While, therefore, inspected milk is guarded by many sanitary regulations, it is not subjected to the same frequency of inspection and examination as certified milk, nor is the prescribed maximum bacterial content nearly so low as in the latter. At the present time, the speaker said, ten barns, representing 800 cows, were producing certified milk, and nineteen farms, representing 700 cows, were producing inspected milk. The inspector employed by the commission had made eighty-six visits to farms, fifty-eight of these farms being at places where it was necessary to remain over night in order to see the milking and bottling. Of the fourteen farms regularly visited three were within thirty-five miles of New York, one was sixty-five miles distant; nine were from seventy-five to ninety miles away, and one was 200 miles from this city. Since January of the present year a monthly charge had been made to the milk dealers in order to defray the expenses of the commission. The charge for the certified farms was based upon the number of cows, and varied from eight to fifteen dollars per month, while for the inspected farms, which are usually situated in groups around a creamery, the charge was one dollar per month and certain expenses. This made the income of the commission about $100 per month. Dr William H. Park had cooperated with the commission, directing the inspections and bacteriological examinations.

Officers Elected.—The following officers were elected at this meeting: *President*, Dr. Charles N. Dowd; *First Vice-President*, Dr. Wendell C. Phillips; *Second Vice-President*, Dr. Rowland G Freeman; *Secretary*, Dr. John Van Doren Young; *Treasurer*, Dr. John S. Warren; *Censors*, Drs. Frank Van Fleet, Henry S Stearns, William H. Park, Floyd M. Crandall, and Joseph Brettauer.

Surgical Suggestions.

Dirty Hands have destroyed more lives than all the implements of warfare. The most important part of the successful treatment of Colles' fracture is perfect reduction. The normal bladder is difficult to infect; the paralyzed and diseased bladder, on the other hand, is very susceptible to infection. Muscular rigidity is a prominent clinical feature of appendicitis, and, as a rule, it is proportionate to the severity and extent of the complicating peritonitis. Enterostomy is a life-saving effort, and as such, no patient should be allowed to die without giving him the possible benefits of the operation.—Senn, in *Practical Surgery for the General Practitioner.*

Sterilization of Catheters.—Nancrede and Hutchins (*American Journal of Surgery and Gynecology*) say: (1) It requires four and one-half minutes to sterilize, by boiling, an infected soft-rubber catheter; (2) Elastic catheters and soft rubber catheters can be boiled repeatedly for five minutes or more without producing roughness or reducing their elasticity; (3) Immersion in bichloride (1-2,000) will not sterilize an infected catheter; (4) Formalin vapors will sterilize infected instruments in twenty-four hours; (5) All methods of sterilization commonly employed should be continued for a longer period than the minimum time required for the destruction of germs in the laboratory.

Mastoid Operations.—The goal in all mastoid operations is the antrum, and this should always be found and entered, and is done by means of the chisel, hammer rongeur-forceps, and spoon. In recent cases it may be sufficient merely to drain the antrum, but ordinarily there has been quite a destruction of the bone, and all the soft bone, granulation tissue, etc , should be removed, and this will often mean the removal of the whole cortex, and all mastoid cells extending down to the tip, at which place there is generally a large cell, and it will often occur that the only pus found will be in this most dependent cell, and it is important that exit be afforded it.—T. H. Halstead in *Philadelphia Medical Journal.*

Tonsillotomy.—I consider operative treatment necessary when the tonsils are so large that they mechanically cause some obstructive symptom, even if otherwise healthy—when they are the centers for frequent or prolonged catarrhal or acute inflammatory attacks; when they are the cause of lymphadenitis; when the crypts and recesses are filled with caseating secretion, which does not yield to treatment; when they are the probable cause of a troublesome reflex cough. I consider it advisable when an adenoid operation is necessary, even if the hypertrophy is not very marked.—F Marsh in *Medical Press*, June 11, 1902.

New Instruments.

A NEW BIVALVE UTERINE DRAIN FOR THE TREATMENT OF UTERINE RETENTION AND STERILITY.*

By A. ERNEST GALLANT, M.D.,
NEW YORK.

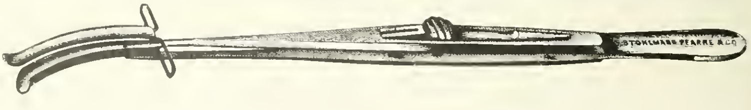
PROFESSOR OF GYNECOLOGY, NEW YORK SCHOOL OF CLINICAL MEDICINE, ETC.

The damming up within the uterus of its normal or any abnormal secretion is generally spoken of as retention. This condition may arise from one or more of several causes, which may be congenital or acquired. Among the former class we find stenoses—vulvular, vaginal, or cervical; displacement, retroversion, and flexions—anteflexion of the cervix or retroflexion of the body. Either of the above conditions may be met with as an acquired condition, and with laceration cicatrices, or neoplasms may interfere with the free exit of uterine secretion.

As might be expected, retention is but rarely met with until menstruation has begun, and but infrequently persists after that function has ceased.

Normally, the uterus lies upon the fundus of the bladder in such a position as to be comparable to a bottle lying obliquely with its mouth downward, so that its fluid contents run down and out (practically oozing drop by drop). But when, as in retroversion, the mouth of the bottle is uppermost, the cavity fills to overflow, the stagnant blood coagulates and, as a foreign body, irritates the uterus to contract, forcing the accumulated blood out, and the woman suffers from uterine colic, and suprapubic and sacral pain.

If, however, the retention be due to flexion, the condition differs in that the mouth of the uterus points downward, but the flexible neck has been bent like a kinked garden hose, and the kink must be straightened out or overcome ere any fluid can pass that point. The menstrual blood soon fills up the small uterine cavity, and thereby excites contractions, which must be strong enough and continue long enough to dilate the cervix—especially the internal os—sufficiently to allow the retained blood to escape. If a clot of sufficient size is passed, the canal will remain patent until menstruation ceases without further pain, but if the dilatation is only partial, the organ will refill and colicky pains recur throughout the greater part of the menstrual period. As a result of this repeated retention, we have prolonged congestion and menstruation, later menorrhagia, metrorrhagia, thickening of the uterine wall, and enlargement of its cavity with all the discomforts incident thereto.



Infection after miscarriage is always associated with deficient drainage. Puerperal uterine infection will but rarely be met with when the uterus is freely discharging its secretion and the fundus is firmly contracted. After-pains indicate retention and insufficient drainage.

Uterine drainage consists of any means whereby the patency of the cervical canal is maintained to facilitate the free exit of normal or abnormal uterine secretions. Primarily a well-drained uterus will but rarely, if ever, be a painful or septic uterus. Thorough uterine drainage depends upon (*a*) proper position of that organ; (*b*) patency of the cervical canal; and (*c*) the maintenance of its patency.

In most instances of simple retroversion, replacement and support of the uterus will give relief from pain, and when no other abnormal condition exists, will be followed by pregnancy. On the other hand, when the displacement has been of long standing, the uterine wall is thickened and its cavity ballooned out, it will be necessary to curette and drain ere the uterus will return to its normal dimensions.

After abortion or miscarriage, whenever the hemorrhage increases rather than diminishes, or the flow continues off and on from day to day, curettage and drainage are imperatively indicated.

In all flexions, whether anteflexion of the cervix or retroflexion of the body, the chief difficulty is found at the internal os, which presents as a thick, tight, hard, inelastic ring, very difficult to dilate to any practical degree. This obstacle has been overcome by inserting a long-handled, blunt-pointed bistoury within the internal os and making shallow incisions in front, behind, and laterally, the dilatation being continued by the introduction of cervical or male sounds up to 36 or 40 F., thus avoiding any danger of cervical rupture.

An efficient drain must be long enough to reach within the internal os, must conform, in a measure, to the shape of the canal, must be rigid enough to prevent the cervix from contracting, and, most important of all, must not plug up and interrupt the outflow.

The bivalve drain represents a split cylinder, and is made open at the sides to overcome the plugging always met with in cylindrical drains, by allowing the cervical mucus to enter the drain through the open sides of the tube and commingling with the other discharge, to prevent coagulation and to wash the cavity clean. Furthermore, cervical mucus is an essential medium in the drain for the entrance of spermatozoa into the uterus.

The bivalve drain has for its foundation the Outerbridge wire stem, the anterior and posterior sections being bridged over to form corresponding halves of the cylinder. By this means the wire does not become imbedded in the cervical tissue, the cervical canal cannot contract to less than the caliber of the drain, nor can the mucous membrane of the canal project into its lumen to occlude it or interfere with perfect drainage. The drain, as made by Stohlman, Pfarre & Co., is one-quarter inch in diameter, and one and three-quarter inches in length; straight or somewhat curved to conform to the cervical canal. The upper ends are flanged and tapered off, and are spread wider apart than the lower part, to prevent the drain from slipping out, and to keep up moderate, spring-like pressure on the internal os. Being made of silver, it can be polished and, after boiling, be used in a series of cases. For use during the puerperium, the drain is made considerably larger—three-eighths inch in diameter and two and one-half inches long. We have made use of only the curved variety in this class of cases.

After dilatation of the cervix, the drain can be readily introduced in the grasp of an ordinary dressing forceps, or any forceps which will enter the lower end of the tube. When the drain has been inserted, before withdrawing the introduction forceps is withdrawn, the drain should be steadied by means of a tenaculum to prevent its dislodgement. It is always well to pack the vagina with sterile gauze after dilatation and introduction of a drain, to maintain the uterus in good position, to steady the drain until the cervix contracts, and to absorb any purulent secretion rather than allow it to be absorbed from the vagina. This packing can, in non-septic cases, remain in the vagina for forty-eight hours, but when any infection is present, it must be changed every day. If the purulent discharge is excessive, the gauze should be removed, and the vagina irrigated every three hours with a solution of potassium permanganate (1:2,000). If the infection has not reached the veins, under this treatment, the temperature will soon subside and the pulse diminish in frequency, both indicating that the patient is improving.

---

*Presented to the Society of the Alumni of the Sloane Maternity Hospital, January 24, 1902.

Initial pain following dilatation, curettage, and insertion of a drain is due to uterine contractions, and is beneficial in that it thereby reduces the size of the uterus; it will subside in a day or two. This fact must be impressed on the mind of the patient.

In cases of constructive dysmenorrhœa or sterility, the drain can be retained in the cervix for several months, but it is well to remove, clean, and replace it after each menstrual period. That portion of the drain at the external os being bathed in the acid vaginal secretion will turn black (oxidation), but this can do no harm.

The bivalve drain has given excellent results: (*a*) in sterility due to flexions, retroversions, and stenosis; (*b*) for the relief of obstructive dysmenorrhœa; and (*c*) for drainage after curettage for endometritis, abortion, miscarriage, retained puerperal products, and the relief of after-pains.

It may not be out of place to utter a warning against the use of the curette and drain in the presence of gonorrhœal vulvitis, urethritis, vaginitis, or endocervicitis, as it is liable to facilitate the introduction of the gonococci into the uterus, tubes, and abdominal cavity.

The Anti-Malaria Campaign in Agro Grossetano.—Giambattista Mariotto-Bianchi describes the methods adopted by a commission appointed by the Government for the extermination of malaria. It has been found utterly useless to attempt to destroy the fully-developed mosquito. For the destruction of the larvæ and the nymphæ in pools, marshes, etc., petroleum in the required amount is too costly, and requires too frequent application, and, moreover, prevents the use of the water by domestic animals. Various other larvacides used possess the same drawbacks, and are in addition easily altered in their composition and lose their effect. Closing all wells, draining the soil, and removing vessels filled with water are efficacious means of relief, but are extremely difficult of application over any extensive area. Individual methods of protection against the mosquito, such as the wearing of veils and gloves are valuable, and were successful in the case of the soldiers who, accustomed to obeying orders, carried out faithfully the instructions given them. But the ordinary populace and the peasants, finding the methods tiresome and inconvenient, could not be prevailed upon to give them a fair trial. Where screens and nets were placed at doors and windows, they paid no attention to them, leaving the doors wide open, removing the springs which closed them automatically, and destroying the nets. It is therefore evident that while, theoretically, malaria can be averted by protection from mosquitos, practically there are so many obstacles to be overcome that protection is not to be obtained.—*Giornale Medico del Regio Esercito.*

Book Reviews.

Diseases of the Nose, Throat, and Ear. By Charles Prevost Grayson, A.M., M.D., Lecturer on Laryngology and Rhinology in the Medical Department of the University of Pennsylvania, etc. Philadelphia and New York: Lea Brothers & Co. 1902.

This book is an attractive one in its make up, with good letter-press work and very few misprints. A serious fault is the use of glazed paper, which makes it trying to the eyes to read by artificial light, and while such paper is necessary for good results in illustration, it should not be used in that part of the text not illustrated. The subject matter is good, and it is, as the author intended it to be, a *practical* book, telling, as he says in the preface, "not only what to do, but how to do it." It is not a reference book, nor an exhaustive academic treatise, attempting to say all that there is to be said, on all branches of the subjects treated.

The parts devoted to anatomy, physiology, and history are brief, and give only the important points; the spaces devoted to pathology might, however, have been increased with advantage.

Under "treatment"—the most valuable part of the book—the author is very evidently and sincerely giving, not compilations from other men's work, but his own experiences—and it is proportionately valuable. Many details of the "how to do it"—just such details as the beginner wants to know and usually has to learn by his own experience and mistakes—are given in a clear and practical way easy to understand; and while some of those details of manipulation and treatment are such as many men, including the present reviewer, have not found entirely satisfactory, the author is, as was stated above, so evidently sincere in his statements of the results of his own experiences, that the differences would be ground for argument, rather than for adverse criticism. One important and welcome feature throughout the book is the insistance upon the value and importance of *general* treatment of the *patient*, as well as the local treatment of the condition in nose, or throat or ear, as the case may be. The author is also to be commended for his conservative and cautious position on the question of operative interference in all cases.

The book is well written and is a serviceable and practical addition to the literature of the subjects treated.

General Paresis, Practical and Clinical. By Robert Howland Chase, M.D., Physician in Chief, Friends Asylum for the Insane; late Resident Physician State Hospital, Norristown, Pa. Pp. 291. Philadelphia: P. Blakiston's Son & Co., 1902.

This book has been written for the general practitioner, especially for the family physician "upon whom," as the author states in the preface, "must rest the responsible decision of diagnosis and early treatment, which, in so many ways, may mean much or little."

The history of the disease is first described, and the succeeding chapters deal systematically with the symptomatology, diagnosis, etiology, pathology, and treatment. It is an admirable compilation, with brief histories of recorded cases abstracted from current literature, portraying the different types of general paresis. The reader will thus gain a comprehensive idea of our present knowledge upon this important subject, as well as much information of practical value.

The book also contains numerous illustrations showing the physiognomy of patients in the various stages of the disease.

Practical Obstetrics. A Textbook for Practitioners and Students. By Edward Reynolds, M.D., Visiting Surgeon to the Free Hospital for Women, Fellow of the American Gynecological Society; of the Obstetrical Society of Boston, etc.; Formerly Instructor in Obstetrics in Harvard University, and Senior Physician to Out-patients of the Boston Lying-in Hospital; and Franklin S. Newell, M.D., Assistant in Obstetrics and Gynecology in Harvard University, Physician to Out-patients, Boston Lying-in Hospital; Assistant Visiting Physician to the Boston City Hospital in the Department of Diseases of Women, etc. Illustrated with 252 engravings and 3 colored plates. Philadelphia and New York: Lea Brothers & Co., 1902.

One begins a review of a new work on Obstetrics with some doubt as to its *raison d'être*. This doubt is speedily dispelled on turning the pages of this admirable guide to practical midwifery.

It is impossible to do justice to it in a short notice. The interest excited by the chapters on the diagnosis and treatment of normal pregnancy, and the management of normal labor, culminates in Part III, which is devoted to Obstetric Surgery. When we state that twelve pages are given to minute directions for the management of posterior positions of the occiput, the expert will infer that at last this much-neglected subject has received the attention which it deserves. We have read this portion of the book, as well as the sections on forceps and version, with interest and profit. Labor in deformed pelves, hemorrhage, eclampsia—all are treated in a thoroughly modern and satisfactory manner. There is no smell of the lamp about this book; it is wholly the product of experience in the lying-in chamber.

The style is clear and forcible, sufficiently dogmatic, but modest and impersonal withal. It is sufficient to add that the book is a worthy exponent of a school of obstetrics noted for its careful, scientific work. We are confident that the profession will be prompt to recognize its singular excellence, and will receive it as the best of its class.

Psychopathological Researches in Mental Dissociation. By Boris Sidis, M.A., Ph.D. New York; G. E. Stechert, 1902.

These researches of 325 pages and ten plates, tracing pulse and respiration, were made in zealously-studied cases, one of mania, one of alcoholic amnesia, two of melancholia, and two of pseudoepilepsy. The work is based on the neuron-theory and the recorded psychomotor manifestations are attributed to dissociation of the neuron-groups. The chief experimental agent used was hypnotism, and the conclusions were reached by introspective and subjectively speculative methods. The generic term, "functional psychosis," is appropriated to indicate a host of phenomena subconscious and not personally conscious. This hypothesis of a cleavage of consciousness into subconscious and personally conscious systems separated by neuron-dissociation, inadequately supported by anatomical or other tangible evidence, enters as a major premise into all the main deductions. Personality also is represented as split in twain or into several effective personalities by functional severance of neuron-aggregates, and like the conscious and subconscious systems is synthetically reunited by hypnotic means.

The author should have given some clear ideas or definitions of the main subjects of research, but he neither analyzes the all-important elements of personality nor the core of the whole matter, viz., the modes and degrees of consciousness. Of hypnotism, his chief agent of research, he describes neither the essential nature, the artificial varieties nor the constant modifications through the personal equation of subject and operator.

With the whole range of urgent and practical psychiatric material at hand, it is a pity that a subject of relative obscurity and inconsequence should have been chosen, and that this work of long expectancy and great promise hould have furnished meager positive results.

Diseases of the Rectum and Anus. Designed for Students and Practitioners of Medicine. By Samuel Goodwin Gant, M.D., L.L.D. Second Edition Rewritten and Enlarged, with 37 full-page Plates, 20 of which are in colors, and 212 smaller Engravings and Half-Tones. Philadelphia: F. A. Davis & Co., 1903.

This work can hardly be described as *multum in parvo*. The considerable bulk of over 700 pages painfully lacks the science of elimination. The essential facts, even when discovered, are smothered in collateral literature of the specialty. In many cases the methods of surgical procedures are so multiple as to be rather confusing than instructive.

Other factors contributing to the ponderability of the book are the 37 plates and 212 illustrations. Some of these latter are new and interesting, and give evidence of original ideas in Anatomy as well as in the Surgery of the part, as, for instance, the relations of the sigmoid colon to the rectum, as shown in fig. 2, p. 6. Other illustrations are of less interest. Fig. 42 shows a very ordinary bedpan, and about half of page 114 is devoted to a rather poor sketch of a Kelly's pad.

The chapter on "Railroading as an Etiological Factor in Rectal Disease" is unique, and treats of new hardships hitherto untouched by Warman, Spearman, and other chroniclers of the vicissitudes of the trainman. The remedy of these evils is not, however, very apparent.

The book, as a whole, is admirably adapted to fill pleasantly the idle hours of the young practitioner. The author has undoubtedly been at the greatest pains to elaborate clearly every detail of his specialty.

Photographic Atlas of Diseases of the Skin. By George Henry Fox, A.M., M.D. Parts VII–XVI. Philadelphia and London: J. B. Lippincott Co., 1900.

This "physician's edition" of the author's larger hand-painted photograph-album has now reached the advanced stage from which the whole work may be fairly judged. That it is highly commendable goes without saying. The author's well-known artistic tendencies and accuracy of reproduction assures work of a high order. The designation attached to particular conditions depicted may not be invariably in accord with the nomenclature usually employed, but the text makes clear the writer's views concerning some of the pityriasic states and scaly dermatites. Especial attention is called to a striking illustration of lichen ruber squamosus, showing the scaly patch in an elongated band, which Hutchinson regarded as so characteristic of this condition, which he called lichen-psoriasis. If the text had been printed smaller, so that the chief points of diagnosis and at least some treatment could have been given for each disease illustrated, it would have made the atlas of much greater value to the majority of subscribers. Even with shortcomings the work stands as an ornament to American Dermatology.

Physical Diagnosis of Diseases of the Thoracic and Abdominal Organs. A Manual for Students and Physicians. By Egbert Le Fevre, M.D., Professor of Clinical Medicine and Associate Professor of Therapeutics in the University and Bellevue Hospital Medical College; Attending Physician to Bellevue and St. Luke's Hospitals; Consulting Physician to Beth-Israel Hospital; Member of the New York Academy of Medicine, etc. Illustrated with 74 Engravings and 12 Monochrome Plates. Philadelphia and New York: Lea Brothers & Co., 1902.

Although there are many works on similar subjects, the author has given us a volume which will no doubt meet with the popular approval of teachers and students of physical diagnosis. Having had a large experience as an instructor, he has incorporated in the text many explanations not ordinarily given by most books, and in so doing answers questions sure to arise in a class-room. We think that his descriptions of the pathological conditions present, and their consequent influence upon physical signs, are especially good, and will serve to make the student a better diagnostician. There are many original illustrations, the importance of which cannot be overestimated in a subject of this kind. The radiographs also are useful to those who have the opportunity of using *x*-rays in their work. The text is particularly well arranged, and is a model of system, which in itself is an excellent example to those who deal with the obscure diseases of the chest and abdomen.

Progressive Medicine. By Hobart A. Hare, M.D., Assisted by H. R. M. Landis, M.D. Vol. III. September, 1902. Philadelphia and New York: Lea Brothers & Co.

This quarterly of advances in the medical sciences contains contributions from Ewart (Thorax and Viscera), Gottheil (Skin and Syphilis), Spiller (Nervous System), Norris (Obstetrics). The general character of abstract work is that usually presented. The illustrations in dermatology are above the average.

Diseases of the Organs of Respiration. A Treatise on the Etiology, Pathology, Symptoms, Diagnosis, Prognosis, and Treatment of Diseases of the Lungs and Air Passages. By Samuel West, M.A., M.D., F.R.C.P., Assistant Physician and Lecturer on the Principles and Practice of Medicine at St. Bartholomew's Hospital; Senior Physician, Royal Free Hospital; Consulting Physician to the New Hospital for Women; Member of the Board of Faculty of Medicine of the University of Oxford; Formerly Physician to the City of London Hospital for Diseases of the Chest; Lettsomian Lecturer at the Medical Society of London; Radcliffe Travelling Fellow of the University of Oxford. In two volumes. With numerous Diagrams and Illustrations. London: Charles Griffin & Company. Philadelphia: J. B. Lippincott Company, 1902.

Although there are many treatises on diseases of the respiratory organs, we feel sure that the two volumes before us will be read with pleasure and profit by all who wish to obtain a complete knowledge of the subject in hand. To those who are making a specialty of the organs of respiration the work is really indispensable. Realizing the importance of a full knowledge of the physiology, anatomy, and mechanics of the lungs, the author begins with a brief but eminently practical exposition of these fundamental principles, together with some accurate definitions of the terms used in physical diagnosis, thus avoiding confusion so often growing out of an uncertain nomenclature. Specially valuable to the clinician are the excellent descriptions of the lymphatics of the lungs, and pleuræ. Following the introductory section are the usual clinical descriptions of the diseases of the larynx, air tubes, lungs, and pleuræ. but these are unusually good, and show the knowledge of a long and faithful experience of a practical worker. Many cases from the note books of the author make the articles more graphic, and give practical illustrations to the text. The sections on treatment are most satisfactory and full. Where a difference of opinion exists, the writer willingly records them, at the same time stating the reasons which have led him to adopt his preferences. The larger sections are given to the ordinary diseases, while the less common affections, at the same time, are afforded sufficient space. High praise is due the diagrams, illustrations, selected statistics, and particularly an almost irreproachable index.

Genito-Urinary Diseases and Syphilis. By Henry H. Morton, M.D., Clinical Professor of Genitourinary Diseases in the Long Island College Hospital; Genitourinary Surgeon to the Long Island and Kings County Hospitals and the Polhemus Memorial Clinic. Philadelphia: F. A. Davis Company, 1902.

New works, in the field of Genitourinary Surgery, are demanded from time to time quite as much as in any other department of special medicine. Advances of the past ten years are not unimportant, making older works and editions incomplete. New works should be better than any that have gone before, both in subject matter and in utility of illustrations. While the ground has been here well covered, and all modern methods and appliances have received due attention, still the lack of artistic merit in the illustrations and the oft-times inadequacy of them to convey the impression sought, makes an unfavorable impression. Devoting a whole page to two small lesions about the nose, which have undoubtedly been touched up before or after being photographed, as on page 301, is a waste of space, which authors should endeavor to avoid. Ten essential lesions of syphilis should have been demonstrated in this same space.

La Prostitution Réglementée et Les Pouvoirs Publics. Par Louis Fiaux. Paris: Felix Alcan, 1902.

This is one of the well-known publications of the *Progrès Médical*, written by a former member of the Municipal Council of Paris, and gives a résumé of methods of control and the powers possessed by public authorities in the principal countries of the two hemispheres. The work is one of especial interest to sanitarians and reformers, as well as to all interested in public morals.

The Practical Series of Year Books. Vol. X. Skin and Venereal Diseases, Nervous and Mental Diseases. By W. L. Baum, M.D., and Hugh T. Patrick, M.D. Chicago: The Year Book Publishers, 1902.

There is some little connection between skin and nervous disorders, and also between venereal and mental, but that is probably not the reason for the combination found in this little year book. This is Vol. X of the series, and maintains, by the character of its abstracts, the standard set by its predecessors, covering the special fields well if not fully. It makes a handy little book to carry about with one, and is vastly more attractive than some of the overweighted year books.

Handbuch der Krankenversorgung und Krankenpflege. Von Dr. G. Liebe, Dr. P. Jacobson, und Dr. Meyer. Berlin: August Hirschwald, 1902.

In the second volume of the first part of this important work the authors present *in extenso* (1078 pages), the novelties, modern appliances, and methods for contributing to the comfort, care, and cure of medical and surgical cases in and out of the hospital. Numerous American devices, hospital equipments, etc., are referred to, and hospital interiors, including some of this country, are depicted. The work abounds in interest and wealth of detail in all matters pertaining to maintenance and care of the sick.

The Dietetic Management of Typhoid Fever.—F. X. Walls says that "milk alone" is objectionable as a typhoid diet: Because it is intolerable as a sole food to the adult in health or disease; because it contains a large amount of poisonous filth; because in digestive tract infections it feeds the parasitic intestinal flora rather than the host; because the systemic intoxication from milk poisoning is so often serious and often fatal; because we have abundant other substances that are without these objectionable features, and are more palatable, equally abundant, as economic, very nutritious, easily digested, and readily assimilated. The author discusses the nutritive and stimulative value of gruels, jellies, broths, egg, etc. He warns against overfeeding, and advises watching the abdomen for gaseous distension of the bowels, and the stools for evidence of indigestion or food putrefaction. If present, the diet should be corrected in preference to the administration of antiseptic or antifermentative remedies.—*The Chicago Medical Recorder*

Cerebrospinal meningitis	. .	2

Rudolf Virchow's Accident and Sickness.—W. Körte, who attended Professor Virchow from the date of his accident (January 4, 1902) until his demise, publishes the first complete authentic account of his last illness which has as yet appeared. Korte first examined the injury in less than one hour after it had been received. The left lower limb was in a position of external rotation and shortened about 3 cm. The region of the left trochanter was very susceptible upon pressure, and all movements caused intense pain. Crepitation was easily elicited, and a diagnosis of fracture colli femoris sinistra intertrochanterica was made. The injured limb was at first laid upon pillows, and, on January 6, a plaster extension bandage, with König's apparatus, was applied, with eight pounds' weight. This relieved the pain to a great extent, and in a few days the patient was able to sit up in bed. The general condition, with the exception of a slight weakness due to shock, was excellent. After three weeks the formation of callus had progressed so favorably that the weight could be removed at intervals with great comfort to the patient. On January 27 and 28 he complained of a stitch-like pain in the left side of the chest. Careful physical examination failed to show any abnormal signs, and, under the application of dry heat, the pain soon disappeared. On February 2 the extension bandage was entirely removed, and the shortening of the limb found to be between 2½ and 3 cm. Massage and resistance movements were instituted, with the result that in about six weeks the patient could use the limb to walk about the room with the help of an attendant and a cane. Despite the favorable course of the injury, the same was not without serious effect upon the patient. During the first few days after the injury mental symptoms appeared. He did not appear, at times, to realize his condition. During such periods he desired to take up his routine work, and made many unreasonable requests. As time progressed, his sleep during the night was very much disturbed, while during the day he lay for quite a portion of the day in a half slumber. These symptoms, however, improved, and on March 23 he went out of doors for the first time. On May 1, during very unfavorable weather, he journeyed to Teplitz, where he took the baths with, apparently, very good result, so that he was able to move about much more freely than before and even to take short walks in the park. He became restless, however, desiring to return to work, and on June 14 proceeded to Harzburg, where he was received with marked honor at the Villa Rautmann. Here, for several weeks, he enjoyed himself greatly. On July 6 he developed quite suddenly an attack of heart failure and dyspnœa. Treatment with digitalis, caffeine, and alcohol did not give good results. The patient gradually weakened and became apathetic, the pulse being small and irregular. No cardiac murmurs were present The urine wrs cloudy and contained some pus. On August 30 he was brought back to Berlin, where he died on September 5, during an attack of heart failure. The primary cause of death was myocarditis, and it is probable that inflammatory renal complications were also present.—*Berliner klinische Wochenschrift*

A Felon. once established, demands only one treatment, thorough and early laying open of the finger with an incision: and, since it has been seen that it is with difficulty that the particular variety is not always easily determined, unless it is, without doubt, a cutaneous or tendinous felon, the point of the knife had better be carried through the periosteum to the bone, thereby giving exit to the pus, infective and destructive material, and giving the greatest relief from pain. Not infrequently this procedure can be done under local anæsthesia, yet, in many instances, it is found more advisable to use a general anæsthetic, thereby relieving the patient of the mental worry, and lessening the shock. The anæsthesia being of such short duration, little or no shock from it would be expected. Necrosed bone, a destroyed joint or tendon, and slough of gangrenous superficial tissue will have to be removed, adding a little time and severity to the operation.—Robert Carothers in *Cincinnati Lancet Clinic*, July 19, 1902.

Anal Fissure.—In pain, confined to any region related, connected, or adjacent to the rectum, look carefully for anal fissure; in severe vesical tenesmus without apparent cause, be on the lookout for the same condition.—*Wisconsin Medical Recorder.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended November 15, 1902:

PARATYPHOID FEVER.*

BY N. E. BRILL, A.M., M.D.,
NEW YORK.
ATTENDING PHYSICIAN TO MOUNT SINAI HOSPITAL.

ON December 1, 1897, I read before the Society of the Alumni of Bellevue Hospital a paper[2] dealing with the clinical aspects of a disease which was similar to typhoid fever, and yet differed from it, chiefly in that its subjects did not show the Widal reaction. There were likewise clinical differences, to which we shall allude later, sufficient distinction existing clinically between the two types of fever, so I believed at that time, to enable a differential diagnosis to be made. For a year preceding the presentation of this disease, of which I had studied seventeen cases, I had been busy with the investigation of the agglutination reaction to which Widal had in that year called attention. An unfortunate endemic of typhoid fever among the nurses at the Training School at Mount Sinai Hospital afforded me the opportunity in the autumn of 1896 to make this study, which was continued, with the assistance of the pathologists at Mount Sinai Hospital, during the summer of 1897, when the typhoid fever cases in my service and in that of my colleagues were unusually numerous. As the result of this investigation, I became early convinced of the specificity of this reaction, and was thus prepared when a number of cases appeared in my wards which presented an analagous picture, clinically, to typhoid fever, but did not show the agglutination reaction, to give these aberrant cases special consideration and thought. Thinking that we had in these aberrant cases a specific infectious disease, we proceeded to conduct a search for the offending organism, and to discover, if possible, its nature. The resources of our laboratory, at that time, were inadequate and insufficient, and the methods of differentiation of these organisms almost unknown. We tried to isolate the infectious agent from the fæces, the urine, and the aspirated blood from the spleen. Our efforts had a decided negative value, in that they established the *absence* of the typhoid bacillus in these cases. The presence of a bacillus which we regarded as a variety of the colon group, but which did not react to the serum of any of the cases, was noted. This organism we did not regard as the *causa morbis.* Notwithstanding the disappointing results of our inquiry, I insisted that the cases under review were not typhoid-fever cases, but were examples of an infection similar to typhoid fever, though this view was opposed by all who, having had occasion to read or hear the published report, had discussed the subject at the various society meetings in which I presented these views. The reasons for maintaining them have been published, and need not now concern us.

This was the first attempt to establish clinically an infectious disease in our nosology which simu- hoid fever, and yet was not due to the Eberth bacillus. Had it not been for the absence of the Widal reaction in such a large number of these cases occurring during the typhoid-fever season, and for the fact that one of these seventeen cases had recovered only six months before from a severe typhoid-fever infection, during which this patient showed the agglutinative reaction, and which was not present during the subsequent disease, I might have passed these cases by without further inquiry, and have classified them as aberrant types of typhoid fever. Permit me, though, to say here that cases of typhoid fever do occur in which the Widal reaction cannot be demonstrated, and to insist that we are not justified in concluding that such cases are not typhoid fever because we cannot elicit the agglutination reaction. The subjection of the blood, urine, and fæces to cultural procedures, and the isolation therefrom of the infectious organism, is the only absolute test.

Since the publication of my paper similar cases have been reported, having the advantage of being supplemented by full bacteriological studies, in which organisms related to the intermediate groups, between the typhoid and the colon bacilli, have been isolated. The most important of these are described by Gwyn,[12] Cushing,[6] Shottmüller,[23] Kurth,[17] Buxton and Coleman,[5] Libman,[18] Brion and Kayser,[3] Hume,[14] Strong,[24] Johnston,[16] Hewlett,[13] Longcope,[19] Hünermann,[15] and de Feyfer and Kayser.[9] The clinical aspect of these cases, however, has received but scant attention, the endeavor of each of these observers being mainly directed to the bacteriology of the disease. Sufficient data have been collected to enable us to form some judgment as to the nature, the morbid anatomy, pathology, and symptomatology of this disease, to which the name of paratyphoid fever has been given.

Nomenclature.—The term paratyphoid fever is unfortunate, as it neither indicates the infectious agent nor the clinical aspects of the disease. Bacteriologists are not yet agreed as to the classification of the bacillus, or whether the organisms isolated from all the cases do not differ greatly among themselves. Some call the bacillus group paracolon, some paratyphoid, hence the former term would have as much claim for the designation of the disease as the latter. If the term paratyphoid is intended to express the idea that, clinically, the disease is like or similar to typhoid fever, the term is etymologically incorrect. From this point of view the affection ought to be called *pseudotyphoid* fever. The term paratyphoid was given to the infection first by Acharde and Bensaude,[1] again by Schottmüller,[23] and Meltzer,[20] and as such the infection has become known.

Bacteriology.—All are agreed that this disease is the result of an infection with a bacillus the position of which is intermediate between the typhoid bacillus on the one hand and the colon bacillus on the other. There are a number of groups or varieties of bacilli between these two extremes. Gilbert suggested the term paracolon to these intermediate groups. Durham,[6] whose exhaustive study of the allied groups cannot be too highly praised, considered that they belonged to the Gärtner[10] enteritidis group (the bacillus of meat poisoning, described by Gärtner in 1888) and its allies. Certain members of this group are pathogenic to man. The one which concerns us being the so-called paracolon or paratyphoid group, of which more than one form, differing among themselves culturally, has been reported. These species are, morphologically, like the Eberth bacillus, from which, in that regard, they cannot be distinguished, and they possess the same motile characters. Unlike the bacillus typhosus, their reaction in milk presents, after a temporary initial acidity, an early alkalinity in the presence of air. Milk is never coagulated by them. They ferment glucose, with the production of gas. They do not ferment lactose, nor do they produce indol.*

---

*Read before the New York State Medical Association, October 22, 1902.

In their reaction to milk they differ among themselves, some producing a less degree of alkalinity than others, after the initial slight acidity, which is common to all, but which itself varies among them as to duration. The main distinguishing features between the intermediate groups, the bacillus coli communis and the bacillus typhosus, are as follows: The intermediates and typhosus do not coagulate milk, the communis does; the intermediates, the paracolon group and the communis, ferment glucose, with the production of gas, the typhosus does not; the bacillus coli communis ferments lactose, with gas production, the paracolon or paratyphoid group and the typhosus do not; the communis produces indol, the intermediates do not, as a rule,* and typhosus does not. The communis and intermediates never react to typhoid serum in high dilutions, whilst the typhosus does in a very large percentage of the cases. In the cases reported where the patient's serum, in high dilutions, gave a specific reaction to both the bacillus typhosus and the specific intermediate isolated from the patient, it is our belief that the cases were double infections, to the possibility of which Meltzer[20] first called attention.

The fact that the intermediates differ among themselves to a great extent culturally, and also in their serum interactions, leaves the matter of their classification still in dispute and *sub judice*. It is for the bacteriologists to further investigate these intermediates before their classification can be settled and before appropriate names can be bestowed upon them. When this is done an appropriate name may be given to the disease induced by them.

History.—The first cases of infection in man by the paracolon group to be reported appeared in France in 1896, the investigators being Achard and Bensaude,[1] who, under the name of Paratyphoid Infections described two cases of continuous fever, the first clinically resembling typhoid fever, with a relapse, a subsequent femoral phlebitis, from the purulent urine of which they isolated a so-called paratyphoid bacillus on two different occasions, though a blood culture was negative. The second case was that of a seven-months' old infant who, after a febrile illness of not quite three weeks' duration, had a suppuration of the right sternoclavicular joint, from the pus of which they isolated an organism resembling that found in their first case. They regarded these organisms as closely resembling the bacillus psittacosis, an organism found in a diarrhœal disease of parrots and communicable to man, and which Nocard[21] first isolated. In man this organism produced a bronchopneumonia with typhoid-fever symptoms

In 1897 Widal and Nobécourt[25] isolated from the pus of an abscess of the neck in a phthisical patient a paracolon bacillus. This patient was thirty-one years old, and had typhoid fever when nine years old. He suffered whilst in the ward of the hospital with only slight constitutional symptoms, and was not regarded as a typhoid-fever suspect.

At the end of the same year I[2] publicly reported my cases, though I was unsuccessful in isolating the disturbing organisms, but I proved that the infection in my cases was not due to bacillus typhosus, though clinically the cases were similar to such an infection. The publication of these occurred on January 8 and January 15, 1898. They may be regarded with a great probability as being cases of infection due to a paracolon bacillus.

Later in the year 1898, Gwyn[12] reported, from Osler's ward at Johns Hopkins, the case of a male who had the classical symptoms of typhoid fever, complicated by three intestinal hemorrhages, in which the Widal reaction was absent, and from whose blood he separated a paracolon bacillus.

Cushing,[6] also of Johns Hopkins University, followed, in 1900, with the next case—that of a man twenty-seven years old, who was supposed to be suffering from typhoid fever, and in whom a chostochondral myelitic abscess developed six months after the fever. The abscess, breaking open, left a sinus, from which, nine months after the fever, Cushing obtained a bacillus belonging to the paracolon group, which he called the bacillus O. The patient's blood never gave the Widal reaction. Cushing's report forms the most thorough and complete study of all reported cases up to this time, and is a splendid example of careful and detailed investigation.

During the same year, Schottmüller[22] reported a case of a patient with a twelve-day fever, roseola and enlarged spleen, but absent Widal reaction, from whose blood he obtained a paracolon bacillus.

In the following year, 1901, he[23] reported a series of five cases occurring during a typhoid-fever epidemic. In these five cases no Widal reaction could be obtained. From cultures made from the blood of each, he isolated similar bacilli. Clinically, his cases were like typhoid fever, though none presented complications or relapses.

In his study of these bacilli, Schottmüller,[23] owing to slight cultural differences, divided them into two groups, Group A and Group B. Those of the former group (two cases) produced a slight amount of acid in litmus whey, while those of the latter (four) did the same, with a subsequent development of alkalinity. The former group grew only indifferently on potato, the latter abundantly.

On the basis of the agglutination reaction with the paracolon bacillus, Schottmüller[23] included a seventh case in his series, the patient being his assistant. This patient's blood readily produced a reaction with the organisms isolated from the other cases, the clinical picture being similar, the Widal reaction being absent.

Kurth,[17] in making serum examinations for the Widal reaction in sixty-two cases of supposed typhoid fever in Bremen, found five that gave no reaction. The bacteriological examination of these five cases showed a bacillus from the urine of one and from the fæces of another which differed from the typhoid bacillus, and which gave agglutinative reaction with the serum of the patient. The serum of the patient from whose urine the bacillus was isolated was not preserved, though the bacillus reacted to the other seven.

On account of the clinical aspect, which, Kurth[17] remarks, was like the old cases described as gastric fever, he called the organism bacillus bremensis febris gastricæ. It was most probably a similar bacillus to the group under discussion, as they were morphologically similar to typhosus, were decolorized by Gram, produced visible gas in the fermentation of glucose, did not coagulate milk, and produced no indol.

---

*The indol reaction cannot be relied on, as Cushing[6] obtained an indol reaction in two members of the intermediate group, and Libman[18] slight reactions with almost all the members of the group he analyzed.

During this year—1902—reports on paracolon infections have multiplied.

Brion and Kayser[3] reported a case in a young girl, in whom they isolated a paracolon bacillus from the blood, urine, fæces, and rose spots. The clinical history of this case, at first, was not like typhoid fever. The girl entered the hospital with a vaginal discharge due to gonococcus, and gave a history of loss of appetite, abdominal pain, and constipation, with slight fever. The spleen was palpable. After two weeks she was discharged, but returned in three days with a renewal of the former symptoms, with a palpable spleen and roseola. This patient had a second relapse, and, during convalescence, a left femoral thrombosis. Her fever lasted nine days, sixteen days, and fifteen days respectively. After the first relapse the fever fell by crisis, and after the second by quick lysis (three days).

Coleman and Buxton[5] report the next case, one from Bellevue Hospital, with a subsequent special complete report on its bacteriology by Buxton;[4] a colored girl of twenty-eight years, who was taken suddenly with a chill, followed by fever, anorexia, and vomiting, subsequently epistaxis and severe headache and a tendency to diarrhœa; later palpable spleen and epigastric tenderness and constipation. Fever broke by crisis on the fourteenth day, and, after the critical fall, showed exacerbations and remissions for another week, when it remained normal. Blood taken from the arm on two occasions gave the paracolon bacillus—Widal reaction was negative.

Following them came a most complete and detailed report, with a bacteriological analysis of all the previous reported cases by Libman,[18] whose work was especially accurate and careful. His case was probably a typhoid-fever case in which a subsequent paracolon infection occurred. Libman[18] isolated from the patient's blood, from the contents of the gall-bladder, and from his urine during life a paracolon bacillus. This bacillus was agglutinated by the patient's serum, and his serum likewise agglutinated bacillus typhosus. Clinically, the case resembled that of a cholecystitis, or liver abscess, with a negative Widal reaction at first, which later became positive in high dilutions. No typhoid bacilli were found. The case terminated fatally, and furnished the first case of paracolon infection which came to autopsy. At the autopsy, healed ulcers in the ileum, as well as ulcers showing a reparative process, were found.

Strong[24], from the Philippines, isolated, post mortem, from the spleen of a soldier who came to autopsy, having died with a supposed typhoid fever, a bacillus similar to Cushing's bacillus O. The organs showed signs of an acute infection, the report of the intestines indicated that they were normal, there being no ulcerations of the ileum.

From Liverpool comes the report of a case by Hume[14] of a man twenty-nine years old, with a clinical history of typhoid fever of fifty-three days' duration, including a relapse, hemorrhage from the bowels, and cystitis, occurring as accompaniments. The Widal reaction was negative. Three weeks after the fever subsided, Hume isolated from the stools a similar bacillus—Bacillus L—which was agglutinated by the serum of the patient. The same was subsequently isolated from the urine. This organism did not produce a late alkalinity in milk. Hume regarded it as belonging to the Gartner enteritidis group.

Next came, in rapid succession, four cases from Johns Hopkins Hospital, reported by Johnston,[16] a case from the New York Hospital, reported by Hewlett,[13] two cases from the Pennsylvania Hospital, in Philadelphia, reported by Longcope,[19] one case being with autopsy protocol.

Finally, Hünermann[15] reports two cases and an endemic of fourteen cases in Eibergen, Holland, described by de Feyfer and Kayser,[9] completes the list to date. They number, in all, sixty-two cases, in at least twenty-five of which the organism was isolated.

		CASES
Acharde and Bensaude	Paris	2
Widal and Nobecourt	"	1

Hume	Liverpool	1
Johnston	Baltimore	1
Hewlett	New York	4
Longcope	Philadelphia	2
Hünermann	Saarbruck	2
De Feyfer and Kayser	Eibergen	14

Morbid Anatomy.—The changes in the tissues indicate an acute general systemic infection, without specific localization. Of course definite conclusions cannot be established from three autopsies, of which even one was of a case of probable double infection. In Strong's and Longcope's cases the large and small intestines showed no ulcerations such as are common to typhoid fever; in fact, they were stated to be normal throughout. Libman's case, which may be regarded as a typhoid-fever case with a subsequent paracolon infection, showed healed and healing ulcers in the ileum. The rest of the organs show the usual changes due to toxæmia and continuous pyrexia; these include cloudy swelling, fatty degeneration and necrosis of their cells. The spleen is enlarged in all cases, its pulp is soft, and the color dark.

The mesenteric glands were enlarged and some hemorrhagic, in Strong's[24] case, while they were normal in Longcope's.[19] The large and small intestines, with the exception of a moderate catarrh and a few superficial hemorrhages in Strong's[24] case, are reported by both these observers to be normal. In the small intestines the solitary follicles and the Peyer's patches showed no changes whatever in either case, a distinctive difference from the characteristic lesion of typhoid fever.

Symptomatology.—An analysis of all these cases will show that the symptoms present mark two groups of cases—the one showing the usual signs of an infection or toxæmia, with so-called typhoid-fever symptoms, accompanied by an involvement of the nervous system, the other beginning more abruptly, with gastrointestinal symptoms, marked chiefly by repeated vomiting and diarrhœa, with fever, which may or may not show the typhoid-fever type. The first group is the more common. It corresponds with the symptomatology of the forms of typhoid fever so closely that it is no wonder that these cases, before the use of the Widal-reaction test were classified as typhoid fever. Yet close clinical observation will detect marked deviations, sufficient, in many cases, to separate the disease from typhoid fever. Whether these deviations from the clinical type of typhoid fever are sufficient, without cultural tests, to identify early this disease remains to be determined. The most of the cases described which belong to this group are almost identical to the clinical picture which I drew from my cases five years ago. This is especially true of Schottmüller's, Kurth's, and Hünermann's cases. My description was as follows:

"A period of three to four days in which the patients complained of loss of appetite, malaise, general weakness, headache, and general body pains, succeeded in many instances by either a distinct chill or chilly sensation, and, in a few, by epistaxis. The patient is feverish, the temperature, as taken in the rectum, rapidly rising to 104° or even 105° F. The period of temperature rise to its acme is within five days. The morning and evening temperature of each successive day of this period being higher than that of the preceding day. On the fourth or fifth day—that is, when the patient's temperature is highest—the following objective signs are present: sensorium dull, the patient apathetic, face flushed, cheeks reddened, *there being a zone of whiteness about the mouth*; eyes dull and expressionless, conjunctivæ congested, the tongue in the greatest proportion of the cases moist and always furred. The fur is thick, *white*, and covers the dorsum of the entire tongue, only the edges and tip of that organ being free from the coating. There are contraction and wrinkling of the brow, owing to the intense headache of which the patient complains. The skin of the body is hot and dry; that of the back, especially over the loins, and the skin of the abdomen are covered by an eruption of rose-red papules. These papules have a diameter of two millimeters, are only slightly raised, disappear, as a rule, completely on pressure, and reappear when the pressure is removed. The papules are not numerous, are lenticular in shape, sometimes acuminated, with a minute vesicle on top, and, while present both over the skin of the back, chiefly between the scapulæ, and over the loins, they are, as a rule, more numerous over the abdomen. Sometimes the eruption is absent.

"The abdomen is slightly distended and rigid, owing to a slight degree of tympanites. There is usually abdominal pain, but little tenderness.

"The spleen is enlarged, and its free border is palpable.

"The bowels, as a rule, are constipated, and can only be moved by some laxative agent. Diarrhœa is only exceptionally present.

"The mental condition of the patient is disturbed. He is apathetic, he does not want to be molested, and lies in a state of drowsiness or semistupor the most of the time. When the fever is highest, toward evening, a few patients become delirious.

"The pulse is full and rapid, occasionally dicrotic.

"The temperature is continuously high, with morning remissions, as a rule reaching 103° to 104° F. in the evening, and falling off two to three degrees therefrom in the morning. The temperature shows these exacerbations and remissions for ten to twelve days from the beginning of the disease, when it suddenly drops, in the large majority of cases, to normal. In a few cases it shows a steplike descent, like the typical typhoid temperature of the fourth week, the descent to normal, however, not taking more than three days. When the degradation of the temperature occurs the symptoms disappear, and the patient feels well but weak. His appetite returns, his headache has disappeared, his tympanites has vanished, he regains his mental composure, and takes acute interest in his surroundings. The bowels now move regularly and without difficulty.

"During the progress of the disease emaciation has developed, and, while not as extreme as it is in true typhoid fever, it is still considerable.

"One of the earliest features of this group of cases is the prostration. It appears earlier, and is more intense, than in unquestionable typhoid, and is often the subject of the patient's complaints. As a rule, these patients are unable, after they take to bed, to sit up without assistance.

"The urine is high-colored and scanty. When subjected to Ehrlich's diazo-reaction, it responds in some cases, and in others not at all. Indican was not present in excess, and was sometimes entirely absent, and acetone and diacetic acid were absent in the cases examined." Some cases show an albuminuria with and others without granular casts.

The blood shows no leucocytosis, a tendency to leukopenia occurring in a number of cases.

The temperature falls by crisis in about 28 per cent. of the cases. This occurs, hence, more frequently than it does in typhoid fever. A short lysis seems to be the rule.

The Gastrointestinal Form.—The second group is marked by cases which begin suddenly with chilly sensations and vomiting, accompanied by general abdominal pain, seldom tenderness. The pain is referred to the right hypochrondrium and the epigastrium. A distinct chill may precede or follow the pain. After the chill, fever develops, the temperature rapidly rising to 104° or higher. Soon diarrhœa supervenes, the movements being thin and watery and rarely accompanied by tenesmus; they contain mucous and sometimes slight traces of blood. Some of these cases develop into the typhoid-fever type, and others continue as above outlined, with a continuous fever showing marked morning remissions until convalescence is gradually established. The diarrhœa may cease gradually or abruptly, and be replaced by a constipation. Weakness and prostration are dominant symptoms. The apathy is not a marked feature in this group as it is in the typhoid form.

It does not seem that the clinical types depend upon the identity of any of the groups of organisms which have been isolated. This may be seen from the fact that Libman's organism, which is practically identical to one of Schottmüller and Gwyn's, was present in a case belonging, clinically, to the second group, while the others were cases of the first group.

Duration.—The duration of the disease varies, the average being a little over two weeks; the limit being ten days and eighty-four days.

Relapses are not infrequent, and occur in about 10 per cent. of the cases. There may be one or two relapses. They are milder than the original attack, and of much shorter duration.

Age.—The youngest case was seven months of age, the oldest sixty years. The age of the greatest number is between twenty-five and thirty-five years.

Sex.—Males are more frequently affected than females.

The time of appearance may occur in any month; the most of the cases have appeared during the months when typhoid fever is most prevalent. Fewest cases appear in the winter.

Geographical Distribution.—Thus far France, Germany, Holland, England, America, and the Philippine Islands have furnished examples of this infection.

Source of Infection.—This cannot, as yet, be determined. It is possible that a few of the cases come from infected meat (meat-poisoning cases). Water may be the means of transmitting it, as is proved by Hünermann's cases.

The severity of the disease varies from mild to intense. When death occurs, it seems to be due to a pure toxæmia.

The complications thus far noted have been venous thrombosis and phlebitis, bronchitis, intestinal hemorrhage, furunculosis, a monarticular arthritis, and a cystitis. As sequelæ have been reported a costochondral osteomyelitic abscess and bacilluria.

Differential Diagnosis.—Five years ago I wrote the following (reserving what has been said whilst describing the symptomatology, the most of the differential data remains true):

"From a general point of view these cases present almost the typical picture of typhoid fever, yet they differ in the following respects:

"In typhoid fever there are premonitory symptoms of a few days' duration· in this group of cases there were none. Our cases show a history of from three to four days' standing before they came under the observation of the physician.

"In typhoid fever there are lassitude and loss of energy; in the other cases there are general body pains of a severe type associated with these.

"In typhoid there is no intense early prostration, as a rule, whereas such is common in these.

"Typhoid is characterized by a gradually increasing daily rise in temperature. In the other group the rise is more sudden, and reaches its acme in from four to five days. In typhoid the highest temperature is reached in the second week of the disease. At the fastigium the temperature in typhoid makes but slight remissions, whereas in these cases there are excursive morning remissions of from two to three degrees Fahrenheit. In typhoid the temperature begins to fall at the end of the third or beginning of the fourth week, or later in protracted cases. The fall is then gradual, the descent, as marked on the chart, being steplike. In these cases the fall, in the largest proportion of those suffering, is sudden, and only in a few was the descent by lysis. In the latter the normal was reached on the third day after the fall began.

"The tongue in typhoid is dry, brown, and furred, while sordes is not uncommon. In these the rule is that the tongue is moist and covered with a white coating. No sordes was observed." Herpes about the lips have since been noted in two cases.

"Abdominal tenderness is common in typhoid, and was not present in any marked degree in these cases. Nor is the tympanites as extensive, neither is it as distressing as in typhoid.

"While the pulse in typhoid is, as a rule, dicrotic, this special quality of the pulse was observed only occasionally in these cases, and that not to a marked degree.

"The most notable difference between the two classes of cases is the length of the disease.

"Emaciation is more extreme in typhoid fever than in this group."

The blood serum in these cases does not react to bacillus typhosus.

Serum Diagnosis.—The question arises, in view of the fact that some observers have suggested the advisability, for diagnostic purposes, of having two varieties of this group as stock cultures for sera tests, whether the serum diagnosis is sufficient to establish the identity of the infection. Inasmuch as Durham[7] has shown many difficulties and variations concerning the rules of agglutination for the ordinary colon group, in this respect differing from the fixed rule for bacillus typhosus, and Cushing and Libman[illegible] similar variations in the intermediate and paracolon groups (thus, serum from Cushing's case would not react with Gwyn's bacillus, though the organisms were apparently identical), it may be said at present that such tests alone are insufficient to establish an absolute diagnosis. Such a diagnosis must, hence, depend upon the recovery of a paracolon bacillus from the blood or from the excretions, or from each.

It is wise to make cultures from the blood early in the disease; that is, as long before the crisis as possible, as, in our experience, in cases in which this infection has been suspected late blood cultures were attended by negative results. The experience of others shows that the bacillus may be obtained from the urine even as long as three weeks after the subsidence of the fever.

Conclusions.—Paracolon infections are not very rare. Thirty-eight cases have been reported during the past year. The infection is a systemic one, and its symptomatology is like that of typhoid fever, from which it can only be differentiated absolutely by the agglutination and cultural tests. The differentiation clinically between the two infections most likely depends upon the superimposed localization of the typhoid infective agent in the intestines in typhoid fever, and its probable absence there in paracolon infections.

The belief that typhoid fever is a specific disease has existed so long that it would be iconoclastic to disturb its place in medical nosology. The fact, however, remains that typhoid fever is not clinically a specific entity; that organisms besides the Eberth-Gaffky bacillus may produce the clinical symptoms of typhoid fever.

*Since writing the above, the subsequent publication of the original article has come to hand. Evidently, Levy and Jacobsthal had knowledge of these cases before their publication, which occurred in the *Munchener medicinische Wochenschrift*, No. 41, October 14, 1902, p. 1692, and No. 42, October 21, 1902, p. 1752. They relate to an endemic, as noted in the text. There were fourteen cases, which occurred in four families, the numbers being, respectively, 5, 5, 2, 2. There were no blood cultures made. The diagnosis was made from the absent Widal reaction and the positive agglutination of Schottmüller's bacillus, Group B, by the serum of one case out of each family. Case 13 reacted to this bacillus, as well as to bacillus typhosus (a double infection, the authors claim), and ran an afebrile course. The transmission of the disease to the various families was by infected water.

48 West Seventy-sixth Street.

Philadelphia County Medical Society, North Branch.—At a stated meeting held November 10, R. H. Bradbury, Ph.D., C.E., presented a communication entitled "Illuminating Gas in Relation to Disease." He pointed out the danger to health and life from the use of gas stoves that do not insure the perfect consumpton of the gas, particularly in small and ill-ventilated rooms. As a result of such imperfect combustion, carbon monoxide is given off, and this is poisonous in a proportion as small as one-tenth of 1 per cent. Carbon monoxide is especially dangerous because it does not manifest its presence by an odor, and it may cause insensibility and death without premonition. The subject was further discussed by Drs. Seneca Egbert, A. B. Hirsh, and Henry Leffman, and the use of oil for heating purposes was commended in preference to gas. Dr. Albert M. Eaton delivered the "Address of the Retiring Chairman."

A REPORT OF A CASE OF SUCCESSFUL SUTURING OF THE HEART, AND TABLE OF THIRTY-SEVEN OTHER CASES OF SUTURING BY DIFFERENT OPERATORS WITH VARIOUS TERMINATIONS, AND THE CONCLUSIONS DRAWN.

By L. L. HILL, M.D.,
MONTGOMERY ALA.
SURGEON TO THE HILL INFIRMARY.

Henry Myrick, negro, thirteen years of age, of rather delicate appearance, was stabbed at five o'clock Sunday afternoon, September 14, 1902. About six hours after the injury Drs. Parker and Wilkerson were called, and, perceiving the nature of the case, advised that I should be sent for, and upon my arrival I urged an immediate operation. To this the parents readily consented, and I was assisted in the operation by Drs. Wilkerson, Parker, Michel, R. S. Hill, Robinson, and Washington. The knife blade entered the fifth intercostal space about a quarter of an inch to the right of the left nipple, and penetrating the apex of the heart passed into the left ventricle. The wound was about three-eighths of an inch in length, and from it came a stream of blood at every systole. There was no external bleeding, but his general condition was very unfavorable. The radial pulse was almost imperceptible, and the heart sounds were heard with difficulty. There was a triangular-shaped area of dulness. He had dyspnœa, and was very restless. His extremities were cold, as were his lips and nose. When aroused, he answered questions intelligently, though his countenance showed great distress. Securing two lamps, I removed the boy from his bed to a table, at one o'clock at night, eight hours after the stabbing, and proceeded to cleanse the field of the operation, and place the patient in as favorable a condition as my surroundings in the negro cabin would allow. Commencing an incision about five-eighths of an inch from the left border of the sternum, I carried it along the third rib for four inches. A second incision was started at the same distance from the sternum and carried along the sixth rib for four inches. A vertical incision along the anterior axillary line was made, connecting them. The third, fourth, and fifth ribs were cut through with the pleura. The musculo-osseous flap was raised, with the cartilages of the ribs acting as the hinges. There was no blood in the pleural cavity, but the pericardium was enormously distended. I enlarged the opening in the pericardium to a distance of two and one-half inches, and evacuated about ten ounces of blood. The pulse immediately improved, and was commented upon by Dr. L. D. Robinson, who so successfully and skillfully administered the chloroform. I had my brother, Dr. R. S. Hill, to pass his hand into the pericardial sac and bring the heart upward, and, at the same time, steady it sufficiently for me to pass a catgut suture through the center of the wound in the heart and control the hemorrhage. I cleansed the pericardial sac with a saline solution, and closed the opening in it with seven interrupted catgut sutures. The pleural cavity was also cleansed with a saline solution, and drained with iodoform gauze. The musculo-osseous flap was brought down and stitched in position. The operation lasted forty-five minutes. The patient's pulse on reaching his bed was 145° and respiration 56. I injected strychnine hypodermically, and employed hypodermoclysis and autotransfusion. The following morning, September 15, the boy's pulse was 130° and temperature 102°, and he was slightly delirious. On September 16 there was but slight change in the temperature and pulse, though the delirium was much worse. On September 17 he commenced to improve, and his recovery has been uninterrupted. I allowed him to sit up on the fifteenth day. Dr. E. C. Parker, who assisted me in the subsequent management of the case, examined the urine frequently, but was only able to find once a trace of albumin.

Wounds of the heart may be either non-penetrating or penetrating, injuring the cardiac wall or opening a cavity. The chief dangers from the former are shock and injury to a coronary artery. Ninety per cent. are penetrating, and of these only 19 per cent. are immediately fatal. The right ventricle is most frequently injured, and the left auricle is least so. Auricular wounds are more fatal than ventricular ones, and injuries to the apex are less dangerous than either. A needle puncture will rarely cause hemorrhage from a ventricle, but excessive bleeding, which is mostly systolic, is liable to follow a like injury to an auricle. A wound inflicted during diastole is less dangerous than a similar injury during systole, perpendicular wounds are more fatal than diagonal, and those of the right heart bleed more profusely than those of the left. The presence of the foreign body in the heart, the size of the wound, the location of the wound, the number of wounds, the connecting cavities, the attending syncope, and the involvement of Kronecker's coordination center are important factors in determining the outcome. Pericarditis, myocarditis, endocarditis, cerebral embolism, and empyema are frequent secondary complications. When the wound heals there is a possibility of cicatricial stretching, and

	OPERATOR AND YEAR.	LOCATION OF EXTERNAL WOUND.	CHAMBER WOUNDED AND SIZE OF WOUND.	TIME OF OPERATION AFTER INJURY	ANÆSTHETIC.	RESULTS AND REMARKS.
1	Farina 1896	Just above the margin of the left sixth rib, near the sternum.	R. V., ¼-inch; 3 stitches	....	....	Death on sixth day, from bronchopneumonia.
2	Cappelen 1896	Fourth left intercostal space in mid-axillary line.	L. V., ⅘-inch.	1 hour.	....	Death after several days, from pericarditis: branch coronary artery cut.
3	Rehn. 1896	Fourth left intercostal space near sternum.	R. V., 3 stitches.	Following evening.	....	Recovery, empyema.
4	Parozzani ... 1897	Seventh left intercostal space in mid-axillary line.	L. V.; ¾-inch: 4 stitches.	5 hours.	None.	Recovery
5	Parozzani	Third left intercostal space.	L. V.; ⅜-inch; 2 stitches.	½ hour.	None.	Death on second day from anæmia(?) Interventricular septum had been cut.
6	Fumni 1898	Under left nipple.	Apex; cavity not opened, 1 stitch.	Several hours	....	Recovery; empyema.
7	Ninni.... ... 1898	Fifth left intercostal space.	L. V.; 3 stitches.	Quickly.	None.	Death on table.
8	Parlavecchio 1898	Fifth left intercostal space.	L. V.; 1½-inch, apex. 4 stits.	8 hours.	Chloroform	Recovery.
9	Giordano . . 1898	Second left intercostal space	L. V., ⅘-inch; 4 stitches.	½ hour.	None.	Death on nineteenth day from empyema; abscesses of right lung.
10	Nicolai 1899	Fourth left intercostal space, middle way between margin of sternum and nipple	R. V.	1½ hour.	Y .	Death after twelve hours.
11	Tuzzi.	Fourth left intercostal space.	Two wounds; one non-penetrating.	....	None.	Death on twenty-second day from empyema; pericarditis.
12	Longo	Fifth left intercostal space; ⅜-inch internal to nipple.	L. V.; 3 stitches.	At once.	None.	Death in fifteen minutes.
13	Ramoni..........	At third left cartilage; ⅜-inch from sternum.	R. V.; two wounds; one non-penetrating; 4 stitches.	....	None.	Recovery.
14	Marion 1899	Shot through breast.	R. V.; catgut sutures.	....	....	Death.

20	Pagenstecher. 1899	Fourth left intercostal space beneath the nipple.	L. V.; 1⅔ inch; near apex; 3 celluloid stitches.	16 hours.	None.	Recovery.
21	Nanu. 1900	Third intercostal space, 4 cm from edge of sternum.	R. V.; 2 cm. long; 2 interrupted sutures.	....	....	Death on fifth day from infection of pericardium and pleura.
22	aselli.. . . 1900	Below and internal to left nipple, cutting sixth rib.	L. V.; near apex; 2 stitches.	1½ hours.	None.	Death in twelve hours.
23	Fontan...... 1900	Six wounds with scissors between third and seventh ribs in cardiac regioa	L. V.; 12 mm. long; continuous catgut sutures; 3 stitches.	6 hours.	Chloroform.	Recovery.
24	Nietert 1901	....	R. V.; penetrated; 3 silk sutures.	....	....	Death after thirty-six hours.
25	Vaughan 1901	Fifth left costal cartilage divided.	L. V., 2½ cm. long; continuous silk sutures; 7 stitches	¼ hour.	Ether.	Death on table from hemorrhage about completion of operation.
26	Nietert 1901	Left of sternum.	L. V.; not sure cavity was penetrated; 2 stitches.	....	....	Recovery.
27	Nini. 1901	Left of sternum.	R. A.	....	....	Death in four days; sepsis.
28	Mignon et Sieur 1901	....	R. V.	....	....	Death.
29	Fontan 1901	....	L. V.; catgut sutures.	....	....	Recovered; had empyema.
30	Brenner.... 1901	Left of sternum, near sixth cartilage.	R. V.; 7 cm.	Following day.	Yes.	Death on table; degenerate heart muscle.
31	Watten 1901	Fourth right intercostal space.	R. V.; 3.5 to 4 cm.	....	....	Recovery; right pleura wounded; pneumothorax.
32	Lastaria 1901	....	L. V.	....	....	Died soon.
33	Zulehner. .. 1901	....	L. V.; ½ cm. long.	....	....	Suture tore out at once, and patient bled to death on table; heart showed fatty degeneration.
34	Zulehner. . . 1901	....	R. V.; 1 cm long, sutured with catgut.	....	.	Recovery.
35	Stern 1901	....	L. V.; pistol shot; unable to suture on account of location of wound on posterior surface; closed the opening with gauze.	....	...	Death in thirty minutes.
36	Launay .. . 1902	....	L. V.; anterior and posterior walls, pistol shot; catgut sutures in each	..	...	Recovery, no complications.
37	J H Gibbon . 1902	....	R. V.; one suture	...		Died on table
38	L. L. Hill . 1902	Fifth intercostal space, a little to the right of left nipple	L. V., ¾ inch; one catgut suture.	8 hours.	Chl'form.	Recovery.
39	Stewart. 1902	Fourth intercostal space, half-inch to left of sternum.	L V; ¾ of an inch; six catgut sutures.	At once.	Ether	Death on third day

subsequent rupture, as in a case reported by Izzo, of a man stabbed in the left ventricle, who was conveyed to the hospital, from which he was discharged cured on the twenty-eighth day; a few hours afterward, while lifting a heavy body, he fell and quickly died. At the autopsy the cicatrix of the left ventricle was found ruptured. In addition to injuries of the heart caused by bullets, daggers, knives, needles, and various implements of war, it may be wounded by a fractured rib, by a foreign body that has perforated the œsophagus, or by blows upon the chest. Traumatic ruptures are more frequent after a full meal, as the distended stomach pushes the heart upward and forward, and causes a large area of the organ to be in contact with the thoracic wall and receive the impact.

Newton and Gamgee have collected forty-five cases in which traumatisms caused rupture of the heart without opening the pericardium. All were fatal. Only one of Gamgee's cases survived the injury fourteen hours. The fatality is easily understood, for, there being no exit, as soon as the accumulation of blood exceeds the limit of pericardial distensibility, the cardiac movements are mechanically stopped. The surgeon not only would be justified, but it is his bounden duty to operate upon every one of these cases, for it is more important, if possible, to rescue a drowning heart than to relieve a strangulated hernia. It is possible for a foreign body, as a gun missile, to remain quiescent for years in the myocardium, as in the case of a British officer, reported by Stevenson, who carried a bullet encapsuled for eleven years, or the still more remarkable case of Beers (*Cincinnati Lancet-Clinic*, 1898), of an American soldier who survived the lodgment of a bullet in the wall of the left ventricle for thirty-seven years.

Symptoms.—There is no certain cardinal sign by which an injury of the heart can be denoted, but when we consider the location of the external wound, and the usually profuse hemorrhage from it, if it is large, in connection with other signs and symptoms, it can generally be recognized. The pulse is weak, irregular, and intermittent, and often imperceptible in the extremities. There are pain, pallor, restlessness, and general dyspnœa. Frequent attacks of syncope are common. The mind is clear, but the countenance depicts an anxiety and distress that seemingly would welcome death, with the wintry sterility of the grave, as a sympathizing friend. If there is much blood in the pericardium the heart sounds are indistinct, and percussion elicits increased dulness. With the pulsation of the heart a foreign body, as a needle, may be seen to move under the skin.

I have adopted the convenient tabular form of Prof. Vaughan in presenting the following thirty-nine cases, one of which was not sutured, but Professor Stern attempted to close the opening with gauze. Nine were collected by Professor Vaughan, seven by Professor Sherman, and the remainder by myself, chiefly from Italian literature.

From my own experience, and a careful review of the cases reported above, I have drawn these conclusions:

First.—That any operation which reduces the mortality of a given injury from 90 to about 63 per cent. is entitled to a permanent place in surgery, and that every wound of the heart should be operated upon immediately.

Second.—Whenever the location of the external wound and the attending symptoms cause suspicion of a wound of the heart, it is the duty of the surgeon to determine the nature of the injury by an exploratory operation, as is recommended by Professor Vaughan.

Third.—Unless the patient is unconscious, and corneal reflex abolished, as in Pagenstecher's case, an anæsthetic should be given, and preferably chloroform. Struggling is liable to produce a detachment of a clot, and renew the hemorrhage, as occurred in Parlavecchio's patient.

Fourth.—Never probe the wound, as serious injury may be inflicted upon the myocardium.

Fifth.—Rotter's operation renders access to the heart extremely easy, and should be generally adopted.

Sixth.—Steady the heart before attempting to suture it, either by carrying the hand under the organ and lifting it up, or, if the hole is large enough, introduce the little finger, as Parrozzani did, which will serve the double purpose of stopping the bleeding and facilitating the passage of the stitches.

Seventh.—Catgut sutures should be used, as wounds of the heart heal in a remarkably short time. The sutures should be interrupted, introduced, and tied during diastole, not involve the endocardium, and as few as possible should be passed, commensurate with safety against leakage, as they cause a degeneration of the muscular fiber with its tendency to dilatation and rupture.

Eighth.—In cleansing the pericardium it should be sponged out, and no fluid poured into the sac.

Ninth.—It hardly seems necessary to accentuate the fact of the necessity of perfect cleanliness in these operations whenever the urgency of the case does not require instant intervention, as in the patients of Longo and Ninni.

Tenth.—The wound in the pericardium should be closed, and should symptoms of compression arise, reopen the wound and drain as Rehn did.

HYOSCINE IN THE TREATMENT OF DRUG HABITS.

By HOWARD C. RUSSELL, M.D.,
STAPLETON, N. Y
ASSISTANT SURGEON PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE.

In view of the recently published article by Dr. H. A. Hare on the use of hyoscine in the cure of drug habits, I wish to record the history of a case I have recently treated. During the whole time that this man was under observation, he suffered no well-defined pain; in fact, there was very little evidence, at any time, that he was even uncomfortable; and I am of the opinion that he had been taking more of the drugs than he admitted, rather than less. In spite of the well-known tendency of these cases to relapse, I think that this man is permanently cured, as he seems to be devoutly thankful for his escape and entirely rid of his desire for the drugs.

G. G. A., aged thirty-three; nativity, Georgia; white, single, has been going to sea for the last twelve years as an oiler. The family history is negative. The man has had malaria several times; gonorrhœa once, about ten years ago; otherwise his personal history is negative.

He commenced the use of morphine about five years ago, being induced to begin by his mistress, who was a constant user of the drug. In October, 1901, he added cocaine to the morphine. At one time, he was taking at least sixty grains of morphine *per diem*. Since he began the use of cocaine the morphine has been reduced. At the time of admission to hospital he stated that he used at least thirty grains of each daily. For the last two years he has had no sexual desire. He was in a private sanatorium for thirteen weeks for treatment of his drug habits, and has taken various advertised "drug cures."

Physical examination showed the heart and lungs to be normal; the man was of good frame, and much better nourished than would be expected, considering the amount of cocaine used. Trunk, arms, and legs were more or less covered with the marks left by the injections.

August 27, 11 A.M.—One one-hundredth of a grain of hyoscine was given hypodermically. The patient fell asleep in about half an hour, and did not awaken until 7.30 P.M. Pulse full and strong, about 50. On being questioned he said he felt sick, but did not know how to express himself exactly. If let alone, he would fall into a state of semi-consciousness; if questioned, he would answer rationally, but wanted to be left alone.

8.30 P.M.—Hyoscine, $\frac{3}{200}$ grain, and strychnine $\frac{1}{20}$ grain, were given hypodermically. Pulse 66, good and strong. The pulse fell to 54 in half an hour; the man was not asleep, but in a condition resembling coma.

August 28.—Has been quiet all day up to 4 P.M. Since that time has been restless and wants to go out. Had an attack of vomiting about 7.30 P.M. Another injection was given of hyoscine $\frac{3}{00}$ gr., and strychnine $\frac{1}{20}$ gr.

August 29.—A.M.—The man felt pretty good; pupils were beginning to dilate. Muscles of legs have been twitching a little, but these were relieved by an alcohol rub. Bowels were freely moved with salts. The patient complained of weakness. The pulse had been slightly dicrotic. Digitalin $\frac{1}{100}$ grain, hypodermically, was ordered three times a day, and strychnine $\frac{1}{60}$ every four hours.

August 29, 4 P.M.—The patient rested quietly up to to this hour. The pupils have contracted a little. He complained of pains in his legs and abdomen; but, in spite of his statements, he did not act as though he were uncomfortable. It was strongly suspected that he had obtained morphine in some way, but both nurses positively stated that he had not taken any. He wanted to know how long he had been in the hospital. A hypodermic injection was given of digitalin $\frac{1}{200}$ grain, strychnine sulphate, $\frac{1}{20}$ grain, and hyoscine hydrobromate, $\frac{3}{200}$ grain, and the legs were rubbed with alcohol. The patient fell asleep about twenty minutes after the above dose was given.

11 P.M.—Complained of a dull, heavy sensation in his legs. Did not act as if at all uncomfortable. Hypodermic injections were repeated at 4 P.M.

August 30, 9 P.M.—Rested well after 11.39 P.M. The hypodermic injection was repeated. The patient was very comfortable.

August 31.—Has been sleeping since the last visit.

September 1.—The patient's mind was entirely clear, and he said he had no desire for either drug.

September 2.—Was given $\frac{1}{100}$ hyoscine at 12.30. Rested well.

September 3.—Stated that he did not sleep last night, owing to the cramps in his legs. Was placed on regular diet to-day.

September 5.—Was given twenty grains of trional last night at 8 P.M. Slept well all night. The mind was perfectly clear, but the man felt weak.

September 10.—Since last note, the patient has been up and assisting more or less with the regular ward work. States that he has absolutely no desire for the drugs he has been taking. No medicine has been given since last note. He sleeps naturally.

September 13.—Has improved markedly mentally and physically. Says he never felt better in his life.

September 15.—Was allowed to leave the hospital on a pass. Gone four hours; on his return there was no evidence of his having used either drug.

September 16.—The man was so much improved that he was discharged.

INFLAMMATION AND PERFORATION OF MECKEL'S DIVERTICULUM AS A CAUSE OF SEPTIC PERITONITIS, WITH A REPORT OF TWO CASES OF TYPHOID PERFORATION OF MECKEL'S DIVERTICULUM.

By A. E. HALSTEAD, M.D.,
CHICAGO.
PROFESSOR OF SURGERY, CHICAGO POLICLINIC; ATTENDING SURGEON COOK COUNTY AND CHICAGO BAPTIST HOSPITALS.

PERSISTENT omphalomesenteric remains may produce symptoms in a number of ways, depending upon their degree of completeness. Of the pathological conditions arising from these remains, the most important are:

1. Intestinal obstruction, either acute or chronic.
2. A free diverticulum—that is, one attached to the intestine alone—may descend into a hernial sac, and then, by its presence, complicate this condition.
3. The intestine above an attached, patent diverticulum may become invaginated into the diverticulum, or its mucous membrane may become prolapsed, forming a tumor at the umbilicus.
4. When, as in the most complete form of this defect, the diverticulum forms a tube opening freely at the umbilicus, we have a fecal umbilical fistula.
5. Cysts of diverticular origin are at times formed in the abdominal wall, in the vicinity of the umbilicus, or intraperitoneal, either connected or disconnected with the intestine. Those that develop in the abdominal wall are usually properitoneal or subcutaneous, within or near the umbilical scar.
6. In addition to these cystic tumors, solid adenoid growths are occasionally found about the umbilicus, which are no doubt related in their origin to remains of the vitelline duct. These have been termed, by Lannelogue, diverticular adenoid tumors.
7. A Meckel's diverticulum may become the seat of an acute or chronic inflammation. Acute inflammation may lead to perforation, with local or general septic peritonitis. When the inflammatory process is chronic, thickening of the diverticular walls with circumscribed peritonitis will result, as in chronic inflammation of the appendix and gall-bladder.

In this paper cysts of diverticular orgin and acute and chronic inflammations of this structure will alone be considered. Cysts merit consideration in this connection because, when intraperitoneal, they are often connected with the intestine and become infected, and in this way originate a septic peritonitis.

False or retention cysts of diverticular origin are intraperitoneal, and may be divided into two classes, as their cavity is continuous or discontinuous with the intestinal lumen. Their walls are in every respect like those of the intestine; their contents vary. In those communicating with the intestine, the contents are generally fluid, or hard fecal matter. In closed cysts the contents are often fluid, and vary greatly in character, frequently resembling mucus. In a case described by Tiedemann[1], a pear-shaped, pedunculated cyst, attached to the convexity of the ileum, was found in a full-term fœtus. The cyst measured fourteen and one-half lines in length and seven and one-half lines in width. Its lumen communicated with that of the intestine through an opening that would just admit a small probe. It contained a yellowish-white, flocculent fluid. In another case reported by Housten,[2] a closed cyst, the size of a turkey's egg, was found, filled with what appeared to be hardened fæces. Hennig[3] reports an interesting case of what would appear to be a diverticular cyst. This was found in a new-born infant, and filled the entire abdominal cavity, measuring 8½x5½x4 inches. It lay between the leaves of the mesentery, but did not communicate with the intestine. It contained a pale red, viscid fluid. In its walls were found intestinal glands. Cysts having the structure of intestine are occasionally found in the anterior abdominal wall, somewhere near the umbilicus. Their structure and location suggest their origin from the omphalomesenteric duct. Roser[4] reports a case in which, in a male, a tumor developed near the umbilicus. This was incised, and there escaped a watery fluid. A fistula persisting, a free incision was made, exposing a cavity 6 cm. deep, lined with epithelium. The lining membrane was excised, and in it was found Lieberkühn's glands. The wound healed by granulation.

Inflammation of Meckel's diverticulum, although receiving scant attention by writers and clinicians, nevertheless occurs often enough to warrant consideration as a cause of septic peritonitis. Etiologically, the same agents that excite an inflammation of the appendix will determine nearly the same pathological condition in a Meckel's diverticulum. The difference in the form accounts for the slight variation observed in the effect of an inflammation in the two.

In structure the walls of both are practically the same as intestine. In shape and size they differ greatly from each other. In the appendix the lumen is small compared to the length of the tube, thus rendering it difficult for foreign bodies to enter, and also offering a hindrance to the escape into the intestine of a foreign body, or of the products of inflammation which result from an infection of the mucous membrane of the appendix. On the other hand, the large lumen, frequently equaling that of the ileum, of a Meckel's diverticulum, while permitting easy entrance of fecal matter or a foreign body, also facilitates the escape of the same into the intestine, thus lessening the risks of obstruction and infection. The value of Gorlach, which is by some looked upon as an important factor in preventing the escape of the contents of the appendix into the intestines, has no counterpart in a Meckel's diverticulum.

Inflammation of Meckel's diverticulum may result, (1) from participation of the mucosa in a general inflammatory process involving the mucous membrane of the intestine; (2) from local causes, as obstruction of the lumen from twisting or kinking of the neck, or from foreign bodies and fecal concretions which may lodge in this pouch. Trauma also appears to have been the exciting cause of inflammation in some of the reported cases.

Tuberculous ulcers of Meckel's diverticulum have been observed in two cases. In one the small intestine was also the seat of numerous tuberculous ulcers. In a specimen in the Warren Museum, described by Fitch,[5] a diverticulum two and a half inches long, situated five feet from the ileocæcal valve, shows upon its mucous surface three tuberculous ulcers. In a second case, reported by Dixon,[6] there was found on post mortem examination, in a male who had died of septic peritonitis, a Meckel's diverticulum with two tuberculous ulcers, one of which had perforated, allowing the contents of the intestine to escape into the peritoneal cavity. Other ulcers were found in the ileum. Specific infections of the intestinal mucosa, particularly typhoid fever, may produce inflammation and ulceration of a Meckel's diverticulum. Chauffard[7] details a case of a child of nine years who died from diphtheria complicating typhoid fever. Post mortem examination showed a diverticulum the shape of a glove finger, free at its distal end, in the middle of which was a Peyer's patch, tumefied, but not ulcerated. In the small intestine numerous typical typhoid ulcers were found. In the following case, which occurred in my service at the Cook County Hospital, perforation of a typhoid ulcer in a Meckel's diverticulum, in the fifth week of the disease, was the cause of a fatal peritonitis. The history of this case is as follows:

G—— R——, male, aged twenty-six years, had been treated in the medical wards of the Cook County Hospital for typhoid fever for four weeks. During the last two weeks the disease had pursued a very severe course, with high fever, excessive tympanites, and intestinal hemorrhages. On November 16, 1901, he was suddenly seized with severe abdominal pain and vomiting, and quickly passed into a state of collapse. In this condition he was transferred to my service for operation. The abdomen was opened under spinal anæsthesia five hours after the onset of the symptoms of perforation. The peritoneal cavity was filled with liquid fæces and pus. On examination of the intestine, a deeply-congested loop of ileum was seen in the right side of the abdomen. This was brought out and attached to its convex border; about three and one-half feet from the ileocæcal valve was seen a Meckel's diverticulum two inches in length, and having a diameter equal to that of the ileum. In the tip of the diverticulum was a perforation large enough to admit the tip of the finger; from this escaped intestinal contents. This was closed with silk suture, the abdominal cavity was flushed with decinormal salt solution, and, after search for other perforations, the abdomen was closed, with drainage. The patient's condition appeared to improve during the operation and for a short time afterward, but later the heart began to fail, and he died eighteen hours after the operation. Autopsy showed numerous typhoid ulcers, but no other perforation.

An unpublished case of perforation of a typhoid ulcer of a Meckel's diverticulum occurred in the practice of Dr. Wm. E. Schroeder of this city. To him I am indebted for the following history: A male, aged forty-five years, having a moderately severe attack of typhoid fever, developed symptoms of perforation in the second week of the disease. Immediate laparotomy revealed general septic peritonitis. A perforation was found in the tip of a Meckel's diverticulum. The diverticulum was given off from the ileum about three and a half feet above the ileocæcal valve. Adhesions had formed about the perforation, attaching the diverticulum to the anterior abdominal wall to the right of the median line and half way between the umbilicus and anterior superior spine of the ileum. The diverticulum was free from its attachment to the abdominal wall and the perforation closed by suture. The patient died some hours later. Autopsy showed no other perferations.

In a fairly careful search through the literature, only two cases of typhoid perforation of a Meckel's diverticulum were found recorded. The first was reported by J. H. Galton.[8] The patient, a child aged twelve years, died on the eighth day of typhoid fever, with symptoms of peritonitis. At the autopsy two perforations were found—one of the ileum and a second at the extremity of a Meckel's diverticulum. The diverticulum was one and one-half inches in length, with its distal end free. A second case, reported by Boinet and Delanglade,[9] was that of a female, aged thirty-five years, who, in the early stage of typhoid fever, developed symptoms of intestinal perforation. On opening the abdomen, the peritoneal cavity was found filled with a foul-smelling fluid. The perforation was found in the tip of a Meckel's diverticulum. The diverticulum was 10 cm. long and had a diameter equal to that of the ileum. Treatment consisted in cutting off the diverticulum and closing the opening in the intestine by suture. The patient died six hours later.

In connection with perforations of ulcers of Meckel's diverticulum, it is of interest to note that examination of the tube has shown that the muscular layer is frequently defective at its distal end, thus permitting easy perforation of any ulcer of the mucous membrane at this point.

Perforations following gangrenous inflammation from twisting or traction of the neck of a diverticulum are more common than those from specific ulceration of the mucosa. In these cases there frequently occurs, coincident with the inflammation of the diverticulum, a kinking of the intestine, with obstruction more or less complete at the point of attachment of the diverticulum. Here the symptoms of intestinal obstruction may predominate, and the case is then considered one of obstruction, rather than of diverticulitis. Most of the cases in this group have been reported as obstruction from Meckel's diverticulum.

A typical case of gangrenous diverticulitis is described by Roth.[10] A child, sixteen months of age, suddenly developed symptoms of septic peritonitis, from which it died. At the autopsy a diverticulum was seen attached to the ileum, twenty-six inches above the cæcum. Torsion of the neck had occurred, resulting in gangrene of the diverticulum, with general septic peritonitis.

Other cases of gangrenous diverticulitis have been reported by Ragner,[11] Cazin,[12] Korte,[13] and Fox.[14] In a case recently reported by Swkonski,[15] a child four days old died from acute peritonitis. On post-mortem examination a gangrenous Meckel's diverticulum was found to be the cause of the peritonitis.

While in most of the cases of gangrenous diverticulitis reported the symptoms have been those of intestinal obstruction of a moderate degree of acuteness, in some the onset has been so sudden, and of such a character, as to lead to the diagnosis of obstruction from internal hernia. In these cases the ileus was due to rapid paralysis of the intestine from infection, and the great depression, subnormal temperature, and extremely weak pulse, to the intense toxæmia. In other cases the symptoms of acute, gangrenous diverticulitis closely simulated those of appendicitis, the diagnosis of appendicitis having been based upon the history, which is quite common, of preceding light attacks of abdominal pain, vomiting, tympanitis, and a moderate degree of obstruction. In a case reported by Taylor,[16] a child of six years had had several previous attacks of what was considered appendicitis, and was seized with what appeared to be an attack of acute intestinal obstruction. At the operation an acutely inflamed Meckel's diverticulum, with partial obstruction from kinking and pressure upon the intestine, was found. The diverticulum, which was enormously distended, was gangrenous in places. Other cases of this kind are reported by Hohlbeck,[17] Malgagne,[18] Kramer,[19] and Makens.[20] In the latter case, reported as one of obstruction from a Meckel's diverticulum, there was a typical acute, septic peritonitis from perforation of a gangrenous diverticulum due to twisting of the neck of the diverticulum. The obstruction was the result of the peritonitis.

Foreign bodies lodged in a diverticulum constitute a relatively frequent cause of infection and perforation (of a diverticulum). As in the appendix, the presence of a foreign body or fecal concretion soon leads to a lesion of the mucous membrane of the diverticulum; the entrance of pathogenic microorganisms through these lesions leads to inflammation, and, if the infection is sufficiently intense, to necrosis of the diverticular wall. In the reported cases of diverticulitis from foreign bodies, seeds seem to be commonly found. In a case reported by Korte,[13] an adult male died from acute, suppurative peritonitis. The cause was found at autopsy to be a diverticulum filled with cherry-stones that had perforated. Other cases of diverticulitis from the presence of cherry-stones are reported by Demice[21] and Best.[22]

In Housten's[2] case, besides cherry-stones, hard bodies, probably fecal concretions, were found. These had caused recurring inflammation of the diverticulum, with the formation of adhesions and local peritonitis. Fecal concretions were also found in the case of Galeazzi.[23]

Intestinal round worms were the cause of diverticulitis in the cases of Hohlbeck[17] and Escher.[24] In a case of acute perforation diverticulitis, reported by Henry Blanc,[25] a fishbone, lodged in the diverticulum was the cause of ulceration and perforation.

Trauma seems to be a rare cause of inflammation or rupture of a Meckel's diverticulum. A case is reported by Cramer[26] in which acute, suppurative peritonitis followed a kick from a horse. When the abdomen was opened, a ruptured, inflamed diverticulum was found to be the source of the peritonitis. A similar case, with partial obstruction, is reported by Gaely.[27]

The pathological changes incident to an inflammation of a diverticulum are practically the same as those that occur in appendicitis. In cases in which, from constriction of the neck, free communication between the lumen of the gut and that of the diverticulum is prevented, infection, with swelling of the follicles and round-cell infiltration, marks the initial stage. When the infection continues, ulceration, with perforation at times of all the tunics, or, when the inflammation is sufficiently virulent, diffuse gangrenous inflammation may result. If more chronic in character, formation of new connective tissue, with thickening of the walls, takes place. In a still more advanced stage of the diverticular inflammation, destruction of the entire mucous membrane, with obliteration of the lumen of the diverticulum, may occur, as in one of Cramer's cases. Foreign bodies or fecal concretions usually cause ulceration, which may become the starting point of a diffuse inflammation.

In reviewing the histories of the reported cases of inflammation of Meckel's diverticulum, we find that in none was the cause of the symptoms recognized before the abdomen was opened. In the cases operated upon, the diagnosis of appendicitis or of intestinal obstruction was made. At the present time no symptom or group of symptoms are sufficiently characteristic to permit of a diagnosis of diverticulitis. In the majority of cases the disease runs a course closely simulating appendicitis. In many the diverticulum occupies a position in the right iliac region, close to the appendix. The onset is usually sudden, with vomiting, muscular rigidity and pain, as in appendicitis. In a few cases the symptoms have been those of recurring appendicitis, with the interval between the attacks free from any evidence of disease. In those cases in which the diverticulum is attached to the umbilicus, periumbilical pain and tenderness is some evidence of the disease being located in a Meckel's diverticulum. The presence of an umbilical fistula, tumor, or cyst, is presumptive evidence of other omphalomesenteric remains, which may be the source of infection in circumscribed or diffuse peritonitis.

The Production of Immunity against Tuberculosis in Cattle through "Jennerization."—E. Von Behring inoculated more than twenty grown cattle with bouillon cultures human tubercle bacilli, and in no case was such an inoculation followed by a single symptom of general tuberculosis. Young cattle became seriously ill when the intravenous injection contained more than 0.02 gr. of tubercle bacilli grown on solid media; but intravenous injections of not more than five milligrams of dried bacilli, in the form of a well-prepared emulsion, can be given without hesitation for a first inoculation. The animals thus treated with protective inoculations develop resistance against infection with dried human tubercle bacilli and with a bovine virus. Animals thus treated have also been exposed to natural (epidemiological) infection, without thus far showing any signs of having acquired the disease. The author does not positively assert that the primary inoculation with dried human tubercle bacilli may not need to be followed by an inoculation with modified bovine virus. Neither is he in favor of an extensive application of this method of Jennerization until it has been definitely elaborated and confirmed.—*The Journal of Tuberculosis.*

Definition of Progressive Paralysis; Its Differentiation from Similar Forms of Disease.—Vladimir Tschisch says that general paralysis is a parasyphilitic affection of the entire system; the disease depends on a special state of the syphilitic poison (parasyphilitic): the latter decomposes and diffuses its virulence into every tissue of the body. Anatomico-pathologically, as well as clinically, general paralysis is characterized by a proportionate diffusion of the poison in, and a destruction thereby, of the whole organism: not one organ or tissue is more affected than is the other during the progress of this disease. The functions of the organs are similarly attacked in equal proportions. In progressive paralysis the lesions are of a generalized nature, while in other syphilitic affections (dementia ex luesiane cerebri organica, lues cerebro-spinalis) they are of a focal nature. When some functions seem to be normal we are justified in excluding the presence of general paralysis. The apoplectiform and epileptiform attacks in general paralysis are dependent on temporary exudates. The proper treatment of this dread disease can never be judiciously applied until the nature of the disease is intelligently understood.—*The Journal of Mental Pathology.*

Suicides in France.—The statistics of suicides in France for the last twenty years are summarized in the following little table:

Years.	Total No. of Suicides.	Persons in 100,000
1881–85	7,339	19
1886–90	8,226	21
1891–95	9,237	24
1896	9,260	23
1897	9,356	24
1898	9,438	24
1899	9,952	25
1900	8,926	22

It appears that the normal number of 24 suicides in every 100,000 materially decreased in 1900. During the period 1896–1900 the average number of suicides was 9.086—7,069 men and 2,017 women, or 37 per 100,000 men and 11 per 100,000 women. If we divide the data according to condition, we find the proportion in 100,000 to be unmarried men and women, 33; married men and women, 25; widowers and widows, 62. The liberal professions and the public functionaries, that is the more intelligent classes, furnish the greatest number of suicides, 138 per 100,000, while in the class of industrials the number is but 25.—*The Sun.*

Chronic Enteritis and Enteroptosis, with Special Reference to Treatment.—J. A. Lichty gives directions for the hygienic, dietetic, and medicinal treatment of these conditions which are so closely allied etiologically that he considers them together. If there is a gastric hyperacidity with constipation, magnesia usta, and bicarbonate of soda may be prescribed; or, if there is diarrhœa, calcium carbonate with bismuth subcarbonate or bismuth betanaphthol are indicated. If there is hypo- or anacidity, with constipation, a stomachic tonic like nux vomica, with fluid extract of cascara sagrada, if indicated, before meals, may be all the medication required; or, if there is diarrhœa, dilute hydrochloric acid and pepsin may be used with excellent results. If the symptoms do not yield, it becomes necessary to prescribe symptomatically. The author prefers sulphocarbolate of zinc when there is much intestinal flatus. To this he adds bismuth subgallate if there is in addition a looseness of the bowels. Sodium salicylate is to be preferred to calomel or any other cholagogue. Hydrotherapy, massage, and electricity are beneficial, and in some cases surgery may have to be resorted to.—*International Medical Magazine.*

The Typhoid Bacillus in the Blood in Typhoid Fever, with a Preliminary Report of a Study of Fifty-six Cases.—Ellis Kirk Kerr and F. G. Harris report that in their study so far they have merely determined the presence of a motile bacillus that agglutinates with the blood serum of a patient who has given a good Widal reaction. The bacillus was found in 57 per cent. of the cases. The advantages of this aid to diagnosis are: (1) It is certain, the occurrence of a bacillus that reacts to known typhoid blood being absolutely diagnostic of the presence of an active typhoid infection. (2) It is of value early, before the Widal reaction occurred in twelve of the cases reported; perhaps, even, it may be of use before the roseola appears and the spleen enlarges; its early appearance in relapses bears out this possibility. (3) Finally, it is fairly easy, the most important factor being the avoidance of contamination. The limitations of the method are, unfortunately, such as to limit its application to cases under observation in hospitals. Here, however, an incubator and a plentiful supply of culture material and flasks are all that is needed.—*The Chicago Medical Recorder.*

A EUROPEAN VIEW OF THE TREATMENT OF APPENDICITIS.

In a recent issue of a Continental publication (*Journal de Médecine de Bruxelles*, No. 37, 1902), Broca has given us his ideas upon the treatment of appendicitis, based chiefly on his own experiences with the disease. We may infer that these views are also those of most French and Belgian surgeons, and, as such, must prove interesting in this country. According to Broca, his cardinal principle in handling this disease is to diminish as much as possible the indication for immediate operation, and to increase the chances for what he designates as an *operation à froid*. He does not, of course, claim that appendicitis is a disease in which operation may, in many instances, be avoided entirely, as is done by some advocates of what the surgeon justly considers the dangerous medical treatment of the disease. Broca claims, and supports the claim by figures from his own practice, that, by a careful choice of the time of operation, the mortality may be reduced almost two-thirds, but, admitting this, his mortality rate is still left at the somewhat unsatisfactory figure of 13 per cent. He calls attention to some of the dangers of operating during the acute attack, but we think that he expresses too much fear of interfering with adhesions. In very many cases of acute appendicitis no adhesions have formed by the time operation is clearly imperative, and, in those cases in which the operation shows the infectious process enclosed by peritoneal adhesions, it has long been the practice of American surgeons to exercise great care in sparing these barriers to infection, and to avoid any extended search for what may be left of the appendix. When once the source of infection has been removed and good drainage established, the pelvis peritoneum will take care of itself, unless systemic infection has proceeded so far that phagocytic and eliminative processes have been embarrassed. It is just the condition found in operating upon these acute cases in which there is a localized intense peritonitis, which induces surgeons in this country to believe that early operation is the only rational plan of treatment, and we believe that it is acting upon this principle which has made the general results of the American treatment of appencitis so good. To wait for an *operation à froid* in most of these cases would ensure an *autopsie à froid* a very little later.

Broca expresses the opinion that, in very many instances, the surgeon, by careful watching of the progress of the disease, can judge pretty exactly if and when an operation becomes imperatively necessary, and he is evidently willing to treat many of his patients upon this plan. It would certainly, in a number of cases, require superhuman knowledge and foresight to decide when to operate, and most of us would not care to take the chances when we know by experience how rapidly septic processes sometimes advance, and, above all, how much symptoms may be masked until there is a sudden development and signs of a hopeless general sepsis. This writer thinks, furthermore, that, without signs of pus, we may justifiably postpone operation, hoping that the inflammation will subside, so that an operation may be done under more favorable local conditions at some future time. This reasoning would be more forceful if it were not for the fact that it is almost impossible to judge with accuracy when pus has begun to form, and if Broca himself did not admit that, in most cases in which there is swelling and resistance in the iliac fossa, there is pus present.

With one point made by Broca we cannot agree. He believes that, in some cases, even when a certain amount of pus has formed, it is possible, by proper care and watchfulness, to tide the patient over the necessity of an operation, and that the pus will eventually become innocuous and will be absorbed. It is undeniable that pus will sometimes undergo such changes, but in appendicitis certainly the risk of trusting to the occurrence of such a process is very great—much greater, we believe, than that of a timely operation. When pus is formed in the neighborhood of a diseased appendix, the tendency is for it to increase in amount in almost all cases. In this sort of case, in which it is difficult to judge exactly of local conditions, blood examination for leucocytosis is of great value. On the subject of interval operation, Broca's dictum, we think, is thoroughly sound. When a patient has experienced two distinct attacks, he advises that, in the ensuing period of quiescence, an operation be done, or, if an attack has been severe without previous trouble, he thinks it is best to proceed to an operation as soon as the acute local signs have disappeared. It appears that, if this advice is followed, there will be very little waiting to tide patients over severe attacks, or hoping that purulent accumulations will be absorbed. If we are correct in supposing that the ideas of this surgeon are those of most Continental observers, we may compare their position with that of our own surgeons by saying that we are, perhaps, a little more radical, and, in the case of the disease in question, we think this means a little more thorough and consistent. We have learned to consider appendicitis an exceedingly treacherous and variable condition, and we always feel safer after an operation by a competent hand than before that event. There may be some cases of acute appendicitis which may be safely watched for a time, even with signs of considerable severity, but we do not think that they are more than exceptional. There are, however, sometimes cases characterized by a subacute onset without violent symptoms, in which it is advisable to wait and observe before recommending immediate operative interference.

MOVEMENT AND CARRIAGE OF PATIENTS IN CONNECTION WITH HOSPITAL AND AMBULANCE SERVICE.

A matter of much practical importance in connection with the service of hospitals and ambulances, yet one to which but little attention is generally given, has relation to the movement and carriage of the sick and injured in a manner best calculated to avoid the infliction of discomfort, suffering, and material injury to the patient while being transferred from ground to litter, litter to bed, or while being carried up and down stairs. In but few hospitals is any effort at present made toward instruction on this point. The patient, perhaps suffering from fracture or other injury, in which the least unintentional or unnecessary roughness causes much pain, is usually grasped by the instructed in a manner which places both the patient and bearers at an anatomical disadvantage. The former is held awkwardly and insecurely, and not rarely in such a way as to aggravate, it may be to a considerable degree, the gravity of an existing injury; the latter find their burden unduly heavy and difficult to handle, and fail to effect that perfect coordination of patient and bearers which is to the advantage of both. Properly distributed and concerted action is unfortunately the exception rather than the rule. At training schools for nurses the pupils are thoroughly instructed relative to the care of patients, but are taught nothing relative to their transportation and movement. This duty is delegated to the hospital orderlies, and mistakenly regarded as outside the providence and beyond the strength of female nurses. As a result, the average female nurse, when thrown on her own resources, is unable to even direct and supervise the movement of patients by others to best advantage. The hospital orderlies, on their part, usually rely upon main strength to take the place of concerted action and a proper disposition of bearers, and, through their lack of intelligent coöperation, may often be almost as much of a hindrance as a help to each other. In the military service, on the other hand, the handling and transportation of patients in the most convenient and comfortable manner is regarded as a matter of the first importance, and the members of the Hospital Corps receive thorough instruction on this point according to fixed methods prescribed in the manual of drill. To see these trained men lifting, moving, and carrying patients with varying numbers of bearers, up and down stairs and over obstacles—rapidly, securely, and without injury or discomfort to the patient—is a spectacle calculated to enlighten medical men as to the deficiencies in this respect of the average hospital and ambulance service. No better guide for instruction in this respect can be found than the drill manual for the Army Hospital Corps, which, in regard to the transportation of patients, is not so much a book of military drill as a guide to the most simple and satisfactory methods, instinctively employed by the instructed, in arriving at a necessary result. There is no question but that it would be of much value if practical instruction in the handling and movement of patients, along the lines laid down in this manual, were given to the nurses and orderlies in every training school and hospital.

Egyptian Ophthalmia.

In the accounts given by some of the New York lay journals concerning the prevalence of trachoma in the city and its importation by emigrants from parts of Europe and from the far East, Egypt is mentioned as being the country in which the disease is most common and most virulent. The neighborhood of the Nile has always borne a bad reputation as a district infested with ophthalmia of the most malignant type, and there is no doubt but that at one time its evil name was well deserved. Now, however, according to the Egyptian correspondent of the *Lancet*, the situation has greatly changed for the better in this respect. Writing on the subject, the correspondent says: "Volney, who travelled in Egypt in 1784, said that for every 100 persons he met in the streets of Cairo twenty were blind, ten were one-eyed, and twenty others had their eyes red, purulent, or spotted with leucoma. Savary confirms this by saying that at that time the University Mosque of El Azhar in Cairo contained 8,000 blind persons who were kept there. It is known, too, that a century ago this disease was called Egyptian ophthalmia, because both the French and English armies in Egypt suffered so much from it. Larrey tells us that the greater number of French soldiers suffered from it, and MacGregor, writing in 1804, speaks of 2,000 English soldiers who returned blind to England. But the country has improved so much since those days that it seemed almost ridiculous to see the British troops landing in 1882 with their veils and goggles, and, as a matter of fact, the English Army of occupation has hardly suffered from granular ophthalmia, though there have often been a few cases of mild catarrhal ophthalmia among them."

According to Dr. Eloul Bey, the most common causes of blindness to-day in Egypt among the natives are granular ophthalmia, glaucoma, purulent ophthalmia, and smallpox. In 1884 he was appointed medical officer of the government schools. He then found 85 per cent. to be affected with granular lids, while now the number of students only yield 32 per cent. This great improvement can only be due to gradually increasing reforms in public and personal hygiene.

The Use of the Automobile.

The abuse of the automobile has been reprobated in the severest possible language by the Medical Record and by other journals. It must not, however, be surmised that because the automobilist has in many instances gained for himself a bad name, by his careless disregard for the rights of others, that lay or medical journalists are unconscious of the undoubted uses of the automobile. This form of locomotion is assuredly destined to play a great part in solving the problem of quick transportation. Medical men of all classes of the community will probably be the greatest gainers by the successful development of the automobile. The Medical Record of April 1, 1899, acknowledged this fact editorially, and predicted that the day would come when the motor car would be considered almost indispensable by the busy physician.

The *Lancet* of March 20, 1897, said: "It seems that motor carriages should prove especially useful to the general practitioner, and particularly to the country one, upon whose shoulders the burden of maintaining the two or three horses, with their attendant expenses, falls very heavily. At present the initial cost is large, but, on the other hand, the cost of working them is small, and the country roads of England, unlike those of America, are peculiarly well adapted to their use."

The chief drawback to using a motor car in America is the great cost of an efficient machine, strong enough to stand the wear and tear of bad or indifferent country roads, and the difficulty in its management. The cost of a really good automobile is from $1,800 to $5,000, and the man who will attempt to drive one on a lonely rural road, without understanding its mechanism, and consequently being unable to repair it when an accident occurs, will surely soon come to grief.

A country doctor, who has had a considerable amount of experience with motor cars, lays down the following points for intending purchasers to keep in view: Firstly, every maker will assure you that his car is the best on the market and never breaks down. Secondly, every maker of repute will give a trial run. Before buying try several makers and compare experiences, but do not decide unless you have had at least a twenty-five miles' run, as many of the smaller cars seem excellent when tried over a few miles of good road, but in spite of what the makers say to the contrary, they often fail on a steep hill. My advice, therefore, is get a good car from a good maker; leave experimental cars to men who have time to make experiments, and when you have a car take a personal interest in it."

Despite the primary cost, there is no doubt but that a large saving may be affected by the use of an automobile, provided that, in the country at least, a man can do any ordinary repairs himself. If the owner has not a mechanical turn of mind, or cannot spare the time to spend in acquiring the details of car construction, he will not only be at a very considerable expense, but—if a medical man—may be placed in an awkward position by his inability in these respects. Every medical man who depends upon an automobile to carry on his practice should make himself conversant with its mechanism, so that he can either remedy the fault himself or direct others to do so. The advantages of an automobile over a horse to a city physician in the United States are far more obvious than to a country practitioner.

The Baccelli Treatment of Tetanus.

The October *Medical Magazine* contains the following contribution: "One of the disappointments of modern therapeutics is the frequent failure of the anti-tetanic serum as a curative agent, though it has probably done good service as a prophylactic. It is, therefore, well to remember that there is another mode of treatment, the published results of which compare favorably with those following serum infections, and are far superior to any other. This is the method of carbolic-acid injections introduced by Professor Baccelli of Rome, and since then frequently employed with success in Italy. Some Italian surgeons go so far as to say that the method, at least in the more chronic cases of tetanus, is as certain and as immediately beneficial as is the serum treatment of diphtheria, while Professor Babes of Bucharest, who has had great experience with the disease, and who, as a pathologist, is strongly biased in favor of the serum, has used it successfully in several severe cases and says he can not too strongly recommend it when the serum is not obtainable."

In the Medical Record of October 21, 1899, an editorial appeared on this subject, and the following statement of Professor Babes, quoted from his article on tetanus, in the seventeenth volume of the "Twentieth Century Practice of Medicine," was given: "Through the marked success of experiments on animals suffering from tetanus by carbolic acid, I was induced to try Baccelli's treatment, which, according to Italian observers, at first furnished good results, but is becoming obsolete, probably on account of the modern specific treatment. I am, nevertheless, constrained to mention it, as it has given me such good results. We will see that the statistics of the antitoxin treatment do not show any better results. As a result of my experience, I feel justified in urgently advising the injection of a carbolic-acid solution in all cases in which the tetanus antitoxin cannot be obtained."

Carbolic acid in the treatment of tetanus, notwithstanding the excellent results obtained in the past, has been to a great extent, within the last few years, set aside for antitoxin. Baccelli's experience tends to show that carbolic acid is quite as, if not more, effective as a curative agent in tetanus than is anti-tetanic serum.

A Field of Scientific Interest for Young Medical Men.

We have before called attention to the fact that Dr. Peterson, the New York State Commissioner in Lunacy, has thrown open the fourteen State hospitals to recent graduates from medical colleges and general hospitals, through the two positions in each hospital (twenty-eight places in all), under the title of clinical assistant, where such young medical men may obtain experience and continue their medical and scientific training. The positions are unsalaried, though any who desire to remain in the service may become within a year eligible for salaried posts. Board and lodging is provided during the year of service as clinical assistant. While these are hospitals for the insane, among the twenty-four thousand patients which they contain almost every variety of physical disease is met with. The opportunities offered to these young men are as follows: A vast clinical material for utilization in the study of physical diagnosis; an excellent laboratory in each hospital wherein to carry on routine or research work in chemistry and pathology; and, for those who have especial interest in the subject, an immense field for the study of morbid psychology. There has been a great awakening among the medical men in the hospitals as to the desirability of medical and scientific advancement, so that an atmosphere of medical fervor and earnestness has grown up in all of them which will be stimulating to the student who enters as clinical assistant. For the meritorious promotions are and will doubtless become more rapid. Under its new director, Dr. Adolf Meyer, the newly organized Pathological Institute will give courses of instruction to the medical officers of these hospitals which will add a new stimulus to scientific and professional work in the institutions. The first of these courses is to be given to the medical superintendents of the State hospitals at the Institute on Ward's Island during December.

For the position of clinical assistant no examination of any kind is necessary. There being no salary for this office, it does not come under civil-service regulations. Therefore the places are open to any promising and earnest student with a medical diploma and satisfactory references, who impresses the medical superintendent favorably. He need not be a resident of the State of New York, but may come from any State or country. After or during his year's service without salary, he may, by passing the Regents' examination be placed upon the eligible list of the Civil-Service Commission for the position of medical interne, which pays $600.00 per year.

Further civil service examinations later on lead to promotions to better salaried positions. In throwing open such positions it is the intention to make them desirable for the younger medical men who shall be the chief beneficiaries by the system, and who shall have every opportunity for enlarging their professional experience and knowledge. Incidentally it is hoped that a considerable proportion of the clinical assistants will elect to remain in the service, and thus ultimately benefit the State hospitals by attracting young physicians who are ambitious and likely to do themselves and the State credit in the future. There are eighteen or twenty of these positions still to be filled. Applicants should address themselves to the medical superintendents of the State hospitals which are located as follows: Ward's Island, New York City; Utica; Binghamton; Buffalo; Poughkeepsie; Willard; Rochester; Kings Park; Flatbush; Brooklyn; Central Islip; Ogdensburg; Middletown; Gowanda. The last two are homœopathic.

News of the Week.

The William Pierson Library Association of Orange, N. J.—The first annual dinner of this association was given on Wednesday of last week in the reading room of the Orange Free Public Library. Dr. Thomas W. Harvey, president of the association, stated the object of the association, which was to establish a library in memory of the late Dr. Pierson, and reported the work that had been accomplished looking to that end. Toasts were responded to by Judge Adams and by Dr. Abraham Jacobi, J. H. Huddleston, and M. Allen Starr of New York City. Announcement was made at the dinner that the following addresses will be delivered before the association during the season of 1902-03: Monday, December 1, 1902, Dr. M. Allen Starr, "Arteriosclerosis and Its Effects upon the Nervous System;" Monday, January 12, 1903, Dr. W. Gilman Thompson, "Autointoxication;" Monday, February 2, 1902, Dr. John B. Roberts, "The Pathology and Treatment of Surgical Septicæmia;" Monday, March 2, 1903, Dr. Walter B. James, 'Modern Aspects of Malarial Infection," illustrated by lantern slides; Monday, April 6, 1903, Dr. J. Edward Stubbert, "An Historical Sketch of Some So-called Consumption Cures.'

A Physician's Right to Extra Compensation for Distant Visits.—The question as to whether or not a physician, beginning the treatment of a patient in a summer resort, is under obligation to continue his visits after he has returned home, the patient remaining in the resort, without exacting a larger fee, was passed upon a few days ago in the Supreme Court. The suit was that of Dr. Jacob H. Asch, who sued Charles Goldsmith to recover a bill for medical attendance, in which he charged $15 for each visit paid to the defendant after the time he had left Arverne, where the defendant continued to reside. The defendant held that $15 a visit was too much for the physician to charge after leaving the resort, and that the trips out of town ought to have been charged at the same rate ($3) as visits made when both physician and patient were at Arverne. The jury decided in favor of Dr. Asch, giving him $250, the full amount of his claim, after deliberating for five hours.

Throat Department of the New York Eye and Ear Infirmary.—The directors of this institution have decided to suspend the throat department, although reappointing the staff of laryngologists for another year. This action was necessitated by the overtaxing of the resources of the infirmary by reason of the great increase in the number of cases of trachoma applying for relief. It is suggested that the infirmary rent a house in the immediate neighborhood for the exclusive use of patients with trachoma and other forms of contagious ophthalmia.

The New French Hospital.—The cornerstone of the new hospital to be erected by the French Benevolent Society at 450 West Thirty-fourth street was laid on November 18 by M. Jules Cambon, the departing French Ambassador. The new hospital will be seven stories high, will contain 150 beds and about forty private rooms, with additional wards for children. The cost of the building will be about $260,000, of which sum $200,000 has already been raised. In every particular the hospital will have a modern equipment. Its work will continue under the advice of the present medical board, of which the members are Drs. T. G. Thomas, E. G. Janeway, J. J. Henna, J. A. Booth, G. B. Fowler, Ramon Guitéras, Frank Hartley, and E. V. Agramonte. The new hospital will be non-sectarian, as before, and will have a large dispensary.

Insanitary Churches.—The Department of Health has just completed an inspection of 196 churches in the Borough of Manhattan. Insanitary conditions, bad enough to cause the inspectors to order the faults removed or remedied, were found in twenty-five of them. The defective conditions were found in relation to the ventilation and plumbing in the toilet rooms, and not in the auditoriums.

Dr. Bon Chang has applied to the State Board of Medical Examiners for a license to practise his profession in New York. Dr. Chang is a practitioner of repute after the methods of the Middle Kingdom, and is thoroughly conversant with the properties and uses of the simples of the Oriental materia medica, but it is feared that he may be a little weak when it comes to questions of pathological histology and bacteriology. If he gains the coveted license, he will receive the appointment of physician and surgeon-in-chief to a new hospital which the merchants of Chinatown contemplate establishing in Park street, near Mott street. The hospital will be supported in the Chinese fashion, recently adopted, it is said, by the Stillman Infirmary at Harvard, the members of the colony paying regularly while in health, but enjoying free treatment when ill.

A Chair of Comparative Anatomy at Harvard.—Mr. James Stillman of this city, who recently gave to Harvard University an infirmary for the use of any of the students who may happen to fall ill, has supplemented this and other gifts by a donation of $100,000 for the endowment of a professorship of comparative anatomy. The endowment was formally accepted at a special meeting of the Board of Overseers of Harvard University, held on November 19.

Hygiene in the Barber Shop.—An Italian barber in Buffalo has fallen into the clutches of the law for neglecting the rules of cleanliness. He was arrested for wiping the faces of two customers with a single towel, and, being adjudged guilty in the Municipal Court, was fined $3.45.

Damages for Death from Impure Antitoxins.—A St. Louis jury has awarded a complainant $1,000 damages against the former city bacteriologist for the death of the man's daughter, who died from tetanus after having been inoculated with diphtheria antitoxin provided by the city. Nine other cases are pending, in which damages are demanded aggregating $72,000. The jury held that the bacteriologist of the Health Board alone was responsible for the death of the child.

Prizes for Essays on Tropical Medicine.—Announcement is made in the *Journal of Tropical Medicine* of the offer of three prizes of the value of £10 each for essays on the following subjects: Sivenright prize for the best article on "The Nature and Treatment of Diseases, Exclusive of Acute Dysentery, Affecting the Lower Part of the Large Intestine Occurring in Warm Climates"; Belilios prize for the best article on "The System of Drainage and Sewerage (domestic and municipal) Best Suited for Tropical Climates"; Lady MacGregor prize for the best article on "Critical Examination of the Practical Value of Anti-typhoid Inoculation." Intending competitors must send name, address, and the title of the prize to be competed for to the *Journal of Tropical Medicine* 83 Great Titchfield street, London, W., before February 1, 1903; the essays must be sent to the same address by May 1, 1903, and the names of the winners will be announced in July of the same year. The competition is open to all qualified medical practitioners of any nationality, and essays may be written in English, French, German, Italian, or Spanish.

Prizes for Essays on Ichthyotoxismus.—Two prizes, one of 5,000 rubles ($2,575) and another of 1,000 rubles ($515), have been offered for international competition by the Academy of Sciences of St. Petersburg for papers elaborating protective measures against poisoning by fish toxins. The papers may be written in English, French, German, Latin, or Russian, and must be received by the Russian Minister of Agriculture by October 1, 1903.—*Medical Book News.*

Post-Graduate Study in London.—In the post-graduate issue of the MEDICAL RECORD for June 21, 1902, a misplaced foot-note was responsible for the statement that the Great Ormond Street Hospital for Sick Children, the Brompton Hospital for Diseases of the Chest, the Queen Square National Hospital for the Paralyzed and Epileptic, and the Royal London Ophthalmic Hospital, City Road (late Moorfields), were likely to be connected with the Medical Graduates' College and Polyclinic. We intended to say what has now been effected, that the four special hospitals above mentioned (as well as the London School of Tropical Medicine) were to join the association known as the Metropolitan Schools of Medicine, the office of which is in the West Wing Examination Hall, Victoria Embankment, London, W. C.

A Reception to Dr. Welch, recently elected president of the Medical Society of the State of Pennsylvania, was tendered by the Medical Club of Philadelphia on November 14, and was attended by more than 175 professional friends.

Minnequa Hospital of the Colorado Fuel and Iron Company.—The medical department of this company was organized in 1880, when physicians were engaged at each of the company's workings and a temporary hospital was opened at Bessemer. Two years later a hospital with forty beds was built at Pueblo, and new accommodations were added from time to time, until on April 1, 1901, work was begun on a new hospital, on the shores of Lake Minnequa, at Pueblo. The new hospital, a most complete modern structure, is now ready for occupancy. The hospital, a description of which, with many illustrations, is given in *Camp and Plant*, Vol. II, No. 5, is in the form of pavilions three stories in height. The buildings now in use are three wards, an operating room, an isolation ward, stable, recreation hall, power house, laundry, and physicians' residence.

The Typhoid-Fever Epidemic in Philadelphia. One hundred and forty-eight cases of typhoid fever were reported to the Philadelphia Board of Health for the week ended November 15, with ten deaths, as compared with 124 cases for the previous week, with eight deaths. It is estimated that, altogether, there are about 800 cases of the disease under treatment throughout the city. There were reported, also, eighty-one cases of scarlet fever and sixty cases of diphtheria.

Philadelphia County Medical Society.—At a stated meeting, held November 12, Dr. David D. Stewart read a paper entitled "Medical Aspect of Cholelithiasis," in which he discussed the etiology, pathology, symptomatology, diagnosis, and treatment of gallstones in the biliary passages. Dr. John B. Deaver read a paper entitled "Cholelithiasis," in which the same features of the subject were considered, particular attention being devoted to surgical methods of treatment. The general discussion of the subject was continued by Drs. W. L. Rodman, Edward Martin, James Tyson, John H. Musser, and James M. Anders. Dr. Philip Marvel of Atlantic City read, by invitation, a communication entitled "The Existence of Typhoid Fever in Atlantic City." He pointed out that many cases of this disease are imported, the symptoms appearing within a short time of the arrival of the patients and quite outside the limits of the period of incubation. The sources of water supply were discussed, and shown to be free from contamination. Investigation disclosed, however, that, during last year, a place was utilized for the ripening and fattening of oysters for local consumption close to a point where sewage was discharged into a waterway, and from this source, it was believed, some of the cases arose. As soon as the discovery was made, steps were at once taken to insure a discontinuance of the practice.

Pathological Society of Philadelphia.—At a stated meeting, held November 13, Dr. Alfred Hand, Jr., presented a communication entitled "Autopsy Statistics at the Children's Hospital with Reference to Tuberculosis and Its Etiology." He related that, among 332 autopsies, tuberculosis was found in 115 bodies—34.3 per cent. So far as could be determined, the primary seat of the disease was the bronchial glands in 65 per cent., and the mesenteric glands in 8.7 per cent., while this could not be determined in 24.7 per cent., the disease being more or less generalized or indistinct. In one case the tonsil appeared to be the primary seat. Dr. Joseph McFarland presented specimens of (1) cyst of the cerebellum, and (2) tumor of the pituitary body. Dr. A. G. Ellis read a paper entitled "The Pathology of the Tissue Changes Induced by the *X*-ray; Preliminary Report." Drs. Joseph Sailer and A. G. Ellis presented specimens from a case of pulsating hemothorax. The effusion of blood into the pleural cavity was due to rupture of an aneurysm of the aorta. The heart was bound by adhesions to the pericardium, and hence was not displaced. Drs Leonard Pearson and S. H. Gilliland presented a communication entitled "The Immunization of Cattle against Tuberculosis." They cited experiments as a result of which animals were protected from tuberculous infection by previous treatment, subcutaneously or intravenously, with cultures of attenuated tubercle bacilli. Dr. Bryant exhibited a specimen of multiple abscess of the liver and pylephlebitis secondary to gangrenous appendicitis. Dr. David Riesman exhibited a specimen of cirrhosis of the liver, with greatly enlarged spleen and varicose mesenteric veins. The principal symptoms were ascites and epistaxis. Dr. Riesman exhibited also a number of round worms obtained from a patient suffering from typhoid fever. Some had escaped from the mouth by their own efforts, and others had been vomited. Rupture of one of the parasites permitted the escape of tenous, worm-like bodies, which, on microscopic examination, were found to be the oviducts filled with eggs. Dr. Riesman exhibited further a mass of hair obtained from a pilonidal cyst, situated between the buttocks. Dr. Joseph McFarland exhibited a specimen of enormously hypertrophied and dilated heart, with enlargement and induration of the liver, chronic inflammatory changes in the kidneys, and areas of bronchopneumonia. Dr. McFarland exhibited also a specimen of aneurysm of the renal artery. Dr. G. E. Pfahler exhibited a series of skiagraphs illustrating various forms of dilatation of the aorta.

College of Physicians of Philadelphia.—At a stated meeting, held November 5, Dr. T. Hollingsworth Andrews presented, on behalf of Mr. Howard O. Pancoast, a portrait of the late Dr. Wm. H. Pancoast; and also, on behalf of Mrs. Daniel E. Hughes, an oil painting of an insane patient in the Philadelphia Hospital. Dr. James C. Wilson read an appreciative "Memoir of the Late Dr. J. M. Da Costa." Dr. W. W. Keen exhibited (1) Mikulicz's esophagoscope; (2) Cathelin's instrument for obtaining the urine from the two kidneys separately; and (3) Michel's instrument for uniting the skin by means of metallic clamps instead of sutures. Dr. Charles K. Mills presented a communication entitled "The Surgery of Brain Tumors from the Point of View of the Neurologist, with Notes of Recent Cases." Among the causes of operative failure, he pointed out error in localization, hemorrhage, contusion, shock, and miscellaneous undetermined causes. In some cases it was thought death was attributable to removal of intracranial pressure previously due to the tumor. Dr. Mills dwelt upon the utility of the Stellwagen trephine in cases in which it is applicable. In some instances the dental engine is especially available. In addition to other means, the *x*-rays is a most valuable diagnostic resource. Dr. Harvey Cushing of Baltimore pointed out the wisdom of trephining for the relief of pressure, and of headache, and to avert blindness. The discussion was continued by Drs. W. W. Keen, W. Jos. Hearn, F. X. Dercum, and J. Chalmers Da Costa.

The Temperance Question in France.—An official crusade is about to be instituted in France against the sale of various poisonous essential oils, especially those used in the manufacture of liquors and cordials. The prime minister, M. Combes, himself a physician, some time ago officially asked the Academy of Medicine to formulate a list of poisonous essences contained in liqueurs and cordials, intending when the list is received to submit a bill to the Chamber of Deputies restricting the consumption of these compounds, which, he says, are threatening the vitality of the French race. Liqueurs such as absinthe, chartreuse, and the like are principally aimed at. M. Laborde, who is the chairman of the committee appointed by the Academy to comply with M. Combes's request, favors the absolute prohibition of the sale of all the poisonous essential oils except by druggists on physicians' prescriptions. The leading distillers are said to have raised a fund of $200,000 to avert the contemplated legislation.

Obituary.

WALTER REED, M.D.,

MAJOR AND SURGEON, U. S. ARMY.

Major Walter Reed of the Medical Corps of the U. S. Army, died at the Army General Hospital in Washington, on November 23, at the age of fifty-one years. His death was due to appendicitis, for which an operation was performed on November 17.

Major Reed was born in Gloucester county, Va., in 1851, and was a graduate of the Medical Department of the University of Virginia, and of Bellevue Hospital Medical College in 1875. He was appointed an Assistant Surgeon in the Army the year of his graduation, and at the time of his death was first on the list of majors in the Medical Department of the Army. In 1893 he was appointed Curator of the Army Medical Museum, in Washington. During the Spanish-American war he was a member of the board to investigate typhoid fever in the Army.

In 1900 he was sent to Havana and was placed at the head of the commission appointed to determine, if possible, the cause of yellow fever and the means by which it is spread. Starting from Finlay's theory of the agency of the mosquito in the dissemination of the disease, the commission, by a series of painstaking experiments, demonstrated most conclusively the causal relation of Stegomyia fasciata to yellow-fever epidemics, and disproved the theory that the disease could be conveyed in fomites, or that it was contagious in the ordinary acceptation of the term. Sanitary measures based upon the conclusions of Major Reed's commission have freed Havana from the disease.

Major Reed enjoyed the reputation of being a bacteriologist of the first rank. Upon his return from Cuba he was stationed at the Army Medical Museum as curator, a position he had occupied nine years before, and one for which his attainments eminently fitted him. He was also professor of bacteriology and pathology in the Army Medical School, and lecturer on those subjects in the Columbian Medical College of Washington.

Treatment by the Tourniquet to Counteract the Vasomotor Spasm of Raynaud's Disease.—Harvey Cushing describes the case of a patient who suffered from severe arterial spasm with great pain in the upper and lower extremities. During an exacerbation of pain and asphyxia, chiefly affecting the left arm, a flat rubber bandage was first employed as a tourniquet about the upper arm. After one or two minutes' application there was a vasomotor relaxation, which lasted only a short time, but the patient expressed a sensation of considerable relief. The tourniquet was then applied daily to one or another member, according as the symptoms indicated. Relief to the burning pain in the fingers was so pronounced that after the first few trials the patient was not only very willing to submit to the temporary discomfort of constriction, but would call for it. Improvement in the circulatory condition followed; the patient soon ceased to require morphia to induce sleep, and the attacks became less and less frequent and of decreasing severity. In about six weeks she left the hospital, apparently quite well, having gained ten pounds in weight and having had for the preceding two weeks no recurrence of her distressing symptoms. This treatment depends seemingly in principle upon the physiological "blocking" effect of the elastic constriction on the peripheral vasomotor nerves. This temporary interruption of function allows the terminal arterioles to completely relax and a state of arterial hyperæmia to take the place of the local asphyxia which has resulted from the pre-existing spasm.—*Journal of Nervous and Mental Diseases.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LORD ROSEBERY AT THE UNIVERSITY OF LONDON—BRADSHAW LECTURE—MEDICO-LEGAL SOCIETY—GRAVES'S DISEASE—TYPHOID IN CAMPS—THE LATE MR. LENNOX BROWNE—CANCER RESEARCH—ITEMS.

LONDON, November 7, 1902.

THE Earl of Rosebery, as Chancellor of the University of London, paid a visit, to inspect the new Physiological Laboratory, on Wednesday. Having been conducted through the lecture room, workshop, chemical room, general laboratory, and two rooms assigned to the physiology of the senses, he delivered an address in which he recommended any one in want of a humbling process to go through these rooms under the guidance of Dr. Waller. He would certainly return from the expedition in a chastened state of mind. But whether we understand or not the marvelous appliances, we can realize the aim of those who have established this laboratory, and "we hope to make it the center spot for medical research in London." His Lordship went on to declare that there are few symptoms more wonderful to an observant person than the development of this university, which is a sign full of promise to those who think our nation has gone to sleep. But then, he added, it must compass all the powers of a university, and in the midst of this teeming population, in the center of this world center, it must prove itself worthy of such a position. Lord Rosebery concluded with an appropriate expression of gratitude to Mr. Walter Palmer, to whose munificence the university is indebted for the laboratories.

The Bradshaw lecture was delivered this year at the Royal College of Physicians, and was intrusted, for the first time, to an obstetric physician, Dr. Cullingworth, who devoted it to the consideration of ectopic gestation. He began by giving expression to the debt owed to the sagacity, enterprise, and courage of the late Lawson Tait, among whose many and great achievements he knew of none to compare with the revolution he effected in the knowledge and treatment of the hemorrhages of ectopic gestation. Passing on to the diagnosis, he discussed it from his own experience, and it is the diagnosis of these cases which is of the utmost importance to the general practitioner. The tendency is not to recovery, but to death, and to rapid death. Few cases last longer than forty-eight hours, and Dr. Cullingworth has seen it occur within three hours of the attack. The supreme importance of diagnosis is not likely to be disregarded in the light of recent progress, and in emphasizing it, Dr. Cullingworth was induced to argue that this is the physician's mode of looking at it, while the surgeon naturally strives for perfection in its treatment. He thought the developments of gynecology in a surgical direction have led many to doubt whether the time is not near for regarding it as a branch of surgery rather than of medicine. But he deprecated the idea, and held that the striving after perfection of diagnosis in British gynecology is traceable to its traditional association with medicine. He would, therefore, view its severance from medicine with much misgiving. He hoped the college had no thought of disowning either obstetrics or gynecology, or removing them from the influence which he believed to have been extremely beneficial.

The increase of societies proceeds apace. We have now added the Medico-Legal Society, and Sir J. W. Collins, M.D., gave the inaugural address, as president.

He said the society was intended to promote the advancement of medico-legal knowledge in all its branches, and would welcome as members, not only doctors and lawyers, but also those whose work was concerned with the administration of questions involving some knowledge of both medicine and law. It also invited the cooperation of intelligent laymen. He saw ample scope for such a society, and in medico-legal matters there was ample room for advancement on existing practice. A vote of thanks to the president was moved by Mr. Hopwood, K.C., Recorder of Liverpool, and seconded by Sir James Crichton-Browne, who said the existence of the society was amply justified, and would do eminently useful public work, by bringing on to one plane those who were interested in the principles and practice of law or medicine. He hoped the society would include, among other subjects of consideration, penal discipline, and all the reformatory efforts directed to the abolition of the criminal caste, and bringing back to society those who had erred.

The Royal Medical and Chirurgical Society began the session with an important paper by Dr. George Murray of Newcastle, on exophthalmic goiter, based on 120 cases—110 women and ten men. The earliest age at which the disease began was fifteen, the oldest, sixty-five. The greatest liability seemed from sixteen to thirty-five. The earliest symptom noted was usually the goiter, but in nineteen it was palpitation. The pulse was rapid in all cases, in about half it ranged from 120 to 150—in others from 90 to 200. The rate varied much in individuals at different times. Murmurs were often noted. Exophthalmose was present in 75 per cent. In three cases it disappeared. Nervous tremors were usually present, and restlessness, insomnia, excitement, etc., were noticed almost always; in two cases, hallucinations; weakness was often complained of. Rapid respiration was common. In thirty-five cases a tendency to attacks of diarrhœa. The urine was only examined in nineteen, in four of which albumin was detected, and in three sugar. Irregularity of menstruation was noted in twenty-three of the cases, and loss of flesh in forty-five. Variable as is the disease, a considerable number practically recovered, but scarcely completely. One got well in nine months; another died in a year. As a rule, the condition lasts for years. As to treatment, Dr. Murray was disappointed wth belladonna. Convallaria reduced the pulse-rate more than anything. Bromides aided the nervousness. Thyroid gland aggravated the symptoms, but thymus and suprarenal extract had both been of some use. Arsenic gave good results in small doses. Rest in bed should be insisted on in severe cases, and Weir-Mitchell treatment when emaciation was present.

Dr. Hale White asked if Dr. Murray had observed the state of Peyer's patches in fatal cases, for in three cases he found them enlarged, and this, with severe diarrhœa, might have some meaning. The thymus, too, was often large. The only treatment was rest and quietness in hygienic surroundings. None of the drugs named were of value.

Dr. Wm. Ewart regarded the disease as due to toxins in the alimentary tract, and the treatment should be directed to that. He had noticed gastric dilatation and rheumatism in some of his cases. Arsenic was useful.

Dr. H. D. Rolleston had seen pigmentation so marked as to lead to diagnosis of Addison's disease. He had also seen enlarged spleen—interesting in reference to Dr. White's observation of Peyer's patches. Few cases were met with in the post-mortem room, so that he considered prognosis not so bad.

Mr. Maude said the disease was rare in India, though simple goiter was very common there. He had seen three fatal cases—one died from influenzal pneumonia, one from peritonitis, one from septic endocarditis. Though few died from Graves's disease alone, recovery was seldom if ever complete. He was sceptical as to treatment. Cacodyle preparations were no better than other forms of employing arsenic. Thymus he had seen of some use in diarrhœic cases. Nauheim baths were useless.

Dr. Hector Mackenzie gave some particulars of fifty-two cases. Exophthalmos was absent in two; thyroid enlargement in five; abdominal disturbance was present in all severe cases; albuminuria in six; glycosuria in several, and it was easily produced by giving glucose; death occurred in six, but improvement in many, though relapses often followed. Rest was important, if in pure country air. The usual drug treatment he thought to be of some service.

Dr. S. V. Pearson said that of 4,100 deaths in St. George's Hospital only two were recorded from Graves's disease, both of women, one of twenty and the other of twenty-six years. The first had rheumatism and valvular disease; in the second the thymus was persistent, and the left ventricle hypertrophied and dilated.

Dr. Herringham spoke of cases in which goiter was not present, but, the other symptoms were. He had admitted some doubtful ones to hospital, and later on the thyroid enlarged.

Dr. Newton Pitt thought too grave a view of prognosis prevailed. He had seen very bad cases come round. Recovery might be incomplete, but often a fair degree of health was reached.

Dr. Murray, in his reply, stated that he had not examined Peyer's patches. He had seen thyroid do harm in several cases.

Typhoid fever has ever dogged the march of armies, but even in war time it is not so terrible as formerly. The recognition of water as the chief medium of infection is general, but others must not be overlooked. That seemed the view of nearly everyone at the Medical Society when Dr. Leigh Canney brought forward a paper on the 27th, in which he insisted that his plan for supplying boiled water to troops in the field was all sufficient. He did not, indeed, deny the existence of other avenues of infection, but he minimized their importance. In the discussion that followed, Surgeon-General Sir A. de Renzy said that in Fort William, Calcutta, the death rate was formerly 69.9 to 110 per 1,000, but in 1870 a pure water was supplied, since which the rate has been from 10 to 12. Colonel Davies said at Quetta, one battalion in the direct line of the wind from the excreta trenches, suffered three times as much as the others. Captain M. Dillon mentioned an epidemic in Malta traced to dust from an infected sewer. Professor Firth said his experiments with those of Major Horrocks proved the danger of flies and dust in the field. In civil life the conditions differed, and the bacilli should be destroyed on their escape from the body. Dr. Horton-Smith said the urine of convalescents should be tested, and if bacilli were present, urotropin should be given.

Mr. Lennox Browne died on Sunday, in his sixty-second year. In his younger days he was a teacher of drawing, and exhibited at various water-color exhibitions. This artistic training was of the greatest advantage to him when he determined to enter the profession. He took his M.R.C.S. in 1863. Three or four years later he became private assistant to the late Sir Morell Mackenzie. In 1871, when Mackenzie's "Growths in the Larynx" appeared, the author, in his preface, acknowledged the valuable help received by Mr. Browne, and added "all the laryngoscopic drawings made for me since the year 1867 have been taken from life by him, with great fidelity and artistic skill, and he has made finished drawings of those which I myself had sketched at an earlier date." When he left Mackenzie he established, with the aid of friends, another special hospital (the central throat and ear hospital), and, in 1878, brought out the first edition of his chief work "The Throat and Its Diseases," the numerous colored plates of which, from his own drawings, further illustrated his artistic skill. Subsequently, as rhinology progressed, he entitled later editions "The Throat and Nose, and Their Diseases." He was joint author with Emil Behnke of "Voice, Song, and Speech," which has run through numerous editions. Some years ago, Mr. Browne exhibited the drawings and sketches he made during two voyages to South Africa.

It is officially announced that His Majesty the King has consented to become the patron of the Cancer Research Fund, under the direction of the Royal College of Physicians and Surgeons, and of which the Prince of Wales is president. Dr. Bashford, assistant to Sir T. Fraser of Edinburgh, and who has recently been engaged in research work in Professor Ehrlich's laboratory, has been selected by the executive committee for the post of superintendent, and will begin his work forthwith.

Mrs. S. Lewis has forwarded a third quarterly sum of £2,500 to King Edward's Hospital Fund.

A strange case of suicide by a young doctor was investigated by the coroner on Monday. Mr. A. J. Bennett was studying at St. Mary's Hospital for the Fellowship of the College of Surgeons. He went to bed at eleven o'clock on Thursday, asking his landlady to call him at the usual hour in the morning. He was then found dead in his bed, with a bottle of prussic acid—empty—by his side, which he had obtained the previous day for "experimental purposes." No light was thrown on the affair at the inquest. He was said to have ample means, and to have been cheerful as usual up to the last day.

On Tuesday another inquest was held on a prussic-acid case. This was on a retired doctor, who had once been insane and was addicted to opium, so there is less mystery about it, and the usual verdict was returned.

PHOTOTHERAPY OF TUBERCULOSIS

To the Editor of the Medical Record:

Sir: The very instructive and interesting paper, by Dr. J. W. Kime, on the treatment of pulmonary tuberculosis, in your issue of the 1st inst., is full of hope and encouragement for those who are able to leave home and have the benefit of out-door life, and the exposure to concentrated rays of light, under his careful supervision. The valuable array of cases presented by Dr. Kime are exceedingly satisfactory in their results.

Yet there are thousands of people whose cases are amenable to phototherapy; who go from bad to worse, because they cannot get away from home surroundings, or are unable to make up their minds to devote their entire time to getting well.

I am a thorough believer in the open-air treatment of consumption, in all its forms; yet phototherapy can do a great work when the open-air residence cannot be combined with it. The sunlight is ideal, but in a climate like that of New York and Brooklyn it is not a dependence for systematic treatment. Therefore, artificial light, derived from powerful arc lamps, must be used in this climate. These lamps can be made of any desired candle-power, and their light can be administered with absolute regularity, regardless of weather conditions. The time of exposure should not be more than half an hour—I began by exposing an hour, but find that patients do better under exposures of half that time, but they should be given daily.

I have one lamp of 80 ampère (estimated candle-power, 24,000); one lamp of 50 ampère (estimated candle-power, 15,000), and two lamps of 40 ampère (estimated candle-power, 12,000 each).

In using these lamps, interposing material should be arranged so as to cut out some of the heat rays. These lamps should be horizontal, and the light focused upon the chest of the patient by means of French concave mirror lenses. The lenses used at Fort Dodge Sanatorium are a very poor substitute for this kind of lens. The French reflecting lenses are very expensive, and made of one piece of glass, while those used by Dr. Kime are sectional, and made of small pieces of glass, and, therefore, have little, if any, condensing power.

I doubt if one of these large reflectors will reflect as many rays of light from the sun as I can concentrate on the chest of my patients with an 18-inch French reflector, which gathers the light from a 50 ampère arc lamp. Furthermore, the patient can remain at home, have all the pleasures, conveniences, society, and comfort of home, and, unless in the latter stages of phthisis, attend to business, and live among friends, while undergoing treatment.

The patient can, in a measure, approach to out-door conditions by removing the window sash from the sleeping room, and substituting therefor unbleached muslin, or light-weight of tent duck, securing them in a movable frame, or tacking to the window frame.

This arrangement will insure a free supply of fresh air during the sleeping hours, without any exposure to drafts.

Now add to this proper sanitary regulation, with daily bath, and salt rub. Plenty of plain, wholesome, nourishing food, from the home kitchen, and I am not sure but that we have in these measures a plan of campaign in our warfare with this "white plague" that, in the long run, may accomplish more than the best sanatorium treatment.

We are apt to forget that the transfer of a patient, from home and friends, to live among strangers afflicted with the same malady, may more than counterbalance good effects of out-door life in the best sanatoria.

We, as physicians, in our expectation of the benefit to be derived from climate and special treatment, are prone to forget that the mental condition of our patient may more than counterbalance the good effects of such residence, when it involves the sundering of home ties.

Yet phototherapy may be practised and the patient remain at home.

I have had patients referred to me, who had been to the far South, and had come home expecting to die. These same people have been vastly benefited by the use of the chemical light rays. One man, returning in midwinter, with all the most pronounced symptoms, expecting to die quietly among his friends, was at work in June. Others, with laryngeal ulceration, have received marked benefit from the light treatment, even in the variable weather of our spring months. Of its usefulness in this class of affections, I entirely agree with Dr. Kime.

Dr. Kime refers to the apparatus of Dr. Finsen as similar to his, but they are entirely different. When Dr. Finsen uses the sun as his source of light, he has a French condensing lens, about twelve inches in diameter, and passes the concentrated light through blue water before it impinges on the tissues of patient, thus eliminating the heat rays, and leaving only the blue, violet, and ultra-violet rays; this, he tells me, he has verified by the spectroscope. When he uses the arc light for treatment, he eliminates the heat rays by the use of quartz crystal lenses. Allied to this is the light of Dr. A. W. Minim of St. Petersburgh. In his apparatus, he claims great benefit from the violet ray in the treatment of tuberculous ulcers. I purchased the apparatus, with very little expectation of its being of service in such cases. From my short experience in its use, I can say that it is the best and most satisfactory treatment that I have ever used in large and intractable ulcers. The use of concentrated light in the treatment of pulmonary tuberculosis deserves more attention from the profession than it is receiving

So-called Hypertrophic Tuberculosis of the Intestine.—By this term H. F. Harris refers to those rare cases in which tuberculous lesions of the bowel lead to more or less complete obliteration of the lumen. One case is related with minute details. He then discusses etiology, morbid anatomy, symptomatology, diagnosis, prognosis, and treatment. Concerning the latter, he notes that surgery alone offers any hope, and adds that out of eighty-eight recorded operative cases, sixty have been cured and four improved A bibliography closes the article.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Nov. 20, 1902.

Recurrent Parotitis Following Recurrent Attacks of Appendicitis.—Daniel Fiske Jones reports the case of a young woman who was operated upon for appendicitis, and two days later had a swollen right parotid and went through a double parotitis. She had had two attacks of appendicitis previously, and in both cases this had been followed by double parotitis. Stephen Paget gives the following facts regarding parotitis: Out of 101 cases collected by him ten were due to disease or injury of the genitourinary tract, eighteen to disease or injury of the alimentary canal, twenty-three to disease or injury of the abdominal wall, and fifty to disease or temporary derangement of the generative organs. Thirty-seven out of the 101 died, but all of the original disease or injury and not because of the parotitis. In twenty-five cases of ovariotomy both parotids were effected in nine. Of seventy-eight cases forty-five went on to suppuration and thirty-three resolved.

Notes on the Diagnosis and Treatmant of Early Miscarriages.—L. V. Friedman says that when no part of the ovum is prolapsed through the os, or when the os is not sufficiently dilated to permit the finger to feel the intact or ruptured ovum within the uterus, if the patient's pulse be good in quality and less than 110 beats per minute, treatment should be expectant. When miscarriage is not complete, seldom will one be obliged to wait more than twenty-four hours in order to see either an anatomical change which makes clear the diagnosis, or a change in condition which demands action. Having decided upon radical measures, ergot and the tampon are to be used when indicated. When it comes to emptying the uterus, the finger may often be used instead of the curette, as it leaves the uterine mucosa in a condition much more nearly resembling that of the normal puerperal uterus. The uterine cavity should be thoroughly irrigated with corrosive sublimate (1 to 5,000), formalin ½ per cent. to 2 per cent. and sterile water.

Journal of the American Medical Association, Nov. 22, 1902.

Concerning Some Vaccinal Eruptions.—W. W. Stelwagon divides these eruptions into three classes: (1) Those due to the vaccine virus; (2) Those due to mixed inoculation introduced at the time of vaccination or subsequently, and (3) Those that are sequelæ of vaccination. The most frequent and usually more or less evanescent and harmless of these are the localized or general erythema, urticaria, erythema multiforme, a regional vaccina or vaccina-like eruption, impetigo contagiosa, and a pseudo-erysipelatous or erysipelatous inflammation or other accidental regional dermatitis. The most important of these, dermatologically speaking, are erythema multiforme, urticaria, pemphigoid eruptions, and impetigo contagiosa. Erythema multiforme and urticaria present at any time between the first day and the crusting period, but may, especially the former, appear much later. Behrend believed that there were two periods at which these and most other vaccinal eruptions occurred—in the first three days and not until the eighth or ninth. While this is true to some extent, it is far from being the rule, for there are many exceptions, and the pemphigoid eruptions, to be later referred to, often appear in the third or fourth week, and sometimes one or two weeks after complete healing. Exclusive of the foregoing, there are other skin affections following vaccination, such as eczema (sometimes vaccination seems to lead to the disappearance of a chronic eczema) and psoriasis, Syphilitic inoculation at the present day is rare. In the eruptions commonly observed, such as urticaria and erythema multiforme, Stelwagon believes that the causative factors lie with the virus itself, and are due to either its preparation or its preservation, and possibly to some admixture or changes in the lymph constituents, and are not necessarily of extraneous origin. They are analogous to the factors causing the serum rashes in the early daysof antitoxin.

Medical News, November 22, 1902.

The Significance of the Terms Acute and Chronic.—Allen J. Smith, after discussing this subject with its applications, states that some definition such as the following might well be assumed: Acute, as applied to a pathological process, indicates of such a disease that it runs a fairly regular and limited course; such course being frequently, although not necessarily attended by severity of symptoms, and the limitation being possibly in recovery Chronic may be applied in conditions presenting no definite duration, more or less irregularity in the presentation of symptoms, a variable severity of symptoms, and ordinarily limited only by the death of the patient.

Obsessions; Fixed Ideas; Indecisions; Imperative Conceptions; Abulias; Phobias.—Theodore Diller declares that obsessions are diseases of the cerebral inhibitory apparatus; that is, of the will, if we may presume that the other elements in the reflex are functionating normally It is, however, evident that the afferent or efferent paths or end-organ may be defective, in which case the will would be affected only secondarily or negatively Obsessions may be conveniently divided into five classes (1) of doubt, (2) of fear; (3) of impulse; (4) of miscellaneous ideas; (5) abulias. The obsessions of doubt (*folie du doute*) or indecision are very common, and include beside the doubt concerning insignificant matters those concerning religious and metaphysical subjects. Obsessions of fear are very numerous. Many of them have received special names, *e. g.* pathophobia (fear of disease). Among imperative obsessions may be mentioned kleptomania (impulse to steal). An abulia is a non-action The term is used to describe the lack of power to perform an act which the individual wishes to perform. It is really a reverse or inverse sort of an obsession. It is frequently seen in neurasthenia and hysteria. The writer then enumerates various cases, and speaks of the unwisdom of the prevalent teaching concerning masturbation. He points out to his own patients that this practice is rarely followed by the evil results which are commonly enumerated, and that it is impossible for any one to tell from the face of the masturbator that he has ever indulged in this regrettable practice. He then impresses upon the patient what he does believe concerning this practice. The present general ideas concerning it tend to engender a train of morbid ideas which will do much harm. As to the treatment of the obsessions in general, mental treatment is the most important. Each case must be considered by itself. The physical tone must be kept up. The simple rules of hygiene, the use of hydropathy, massage, and electricity, are all useful The treatment by drugs is of the least importance.

Neurasthenia.—Joseph M. Aiken states that this condition is uncommon before the twentieth and the fiftieth year of life. It is of about equal frequency in the sexes. All forms of nervous energy are affected and fatigue comes more quickly than in health. The vital forces are below par, consequently irritability is more easily established This is especially noticeable in the mental sphere. Neurasthenia is a primary affection of the nervous system. Hereditary defects give a tendency to this disorder. There is no pathological anatomy known that is peculiar to neurasthenia. Diminished dynamic energy and lessened recuperative power in the nervous structures is the condition met. The symptoms are easily ranged under motor or sensory disorders without implication of any special organs, those manifested by some one of the special senses; those centered in the gastrointestinal, circulatory, renal, or reproductive organs, and the psychical form. Berkley's division into the hygienic, dietetic, and medicinal treatment of neurasthenics is an admirable one Slowly sipping a glass of very hot water one-half hour before each meal is often of great benefit to an atonic stomach. Saline and lithia drinks assist in lessening fermentation in the alimentary canal. Hot broth or milk just at bedtime often quiets and induces sleep in a nervous patient. The neurasthenic should be encouraged. Gentle faradization to the muscles is useful, but galvanism to the nerve centers is apt to further exhaust cell-power. Hydrotherapy, rubbing, kneading, and massage of the entire body short of fatigue are extremely useful measures. When recourse is had to drugs, iron is most important. Gentian, or any of the bitter drugs, combined with strychnine and glycerin, are the most useful general tonics. Alkalis are of great service. For hypnotics, trional and the bromides, given in hot milk or broth, are the most useful. Opium and alcohol are to be avoided Constipation is best treated by gradually decreasing doses of salines with increased ingestion of water.

New York Medical Journal, November 22, 1902.

The Prevention of Intestinal Diseases in Infants During the Summer.—C. G Kerley and J. L. Hughes detail their experience during the past summer. Their idea was not only to treat sick children, but to put those showing the first signs of illness on a preventive régime. The cases were in hospital and the nurse in charge was instructed to report any slight vomiting or loose stool Under such circumstances milk was withheld and barley water given In purely intestinal cases castor oil was invariably ordered In the vomiting cases the stomach was washed and calomel given, and if there was diarrhœa a mixture of bismuth and aromatic syrup of rhubarb was given. When the stools and temperature warranted the milk was gradually resumed in from one-fourth to one-sixth of its former strength. Of 278 cases under observation, ninety-two had gastrointestinal attacks, and received the above treatment. Of this latter number two died from enterocolitis. Every attention possible was given to general hygiene. Great care was taken with reference to keeping the milk cool and sweet. The author believes that by the means indicated the large mortality from summer diarrhœa can be largely diminished, and that the disease itself should be looked upon as distinctly preventable.

Ten Instructive Cases for the General Practitioner in Medicine, with Remarks upon the Detection and Relief of Eye-Strain.—A. L. Ranney reports these cases, the leading features of which are as follows: (1) Each case tends to illustrate some special type of manifestation of eye-strain in consequence of reflex disturbances upon the nerve centers. (2) Each case was selected to prove to the profession that a scientific investigation and correction of eye-strain can radically cure, in some instances, cases that are apparently hopeless and incapable of permanent relief by medication. (3) Out of the ten cases reported, several have apparently justified a diagnosis of organic disease of the brain or spinal cord. (4) The record of one case goes to show that chronic diabetes may be excited by eye-strain alone and that the relief of eye-strain may cause a total disappearance of the glycosuria. (5) In one case there were periodical attacks of laryngeal spasm that seemed to imperil life. (6) Two cases forcibly illustrated the relations between eye-strain and neuralgia. (7) Three cases illustrated the relation of epilepsy to eye-strain. (8) Two cases forcibly illustrated the relationship between eye-strain and persistent reflex spasm of a localized group of muscles. Ranney expresses his conviction that careful, long continued, and patient investigation of errors of refraction and anomalies of adjustment of the eye muscles should never be omitted whenever the possibility of a reflex cause may exist as a factor in creating abnormal conditions of the nervous mechanisms, the muscular apparatus, or the viscera.

American Medicine, November 22, 1902.

The Surgical Treatment of Epilepsy.—Roswell Park concludes that: (1) Epilepsy is the last disease to which surgical measures should be indiscriminately applied. In judiciously selected cases, radical operations of various kinds, suited to the individual needs of each case, have given far more satisfactory results than has non-operative or medicinal treatment; (2) Every case must be studied as a problem by itself. The only general laws applying are those regarding the removal of peripheral or local foci of irritation and the destruction of paths of conduction which convey disturbing impulses. In each case we must decide as to the operative methods by which we may best meet these indications; (3) In order to attain the best results, patients should be seen early. It would be well to have every epileptic carefully studied by an accomplished surgeon, who should review the case with a view to the possibility of surgical intervention; (4) Operation, when indicated and undertaken, should be regarded as a first measure to be followed, and often preceded, by others looking to a correction of all faults of diet, of elimination, etc. Long continued attention to these matters is the price of eventual success; (5) In those cases characterized by blanching of the face, when the seizures can be warded off or mitigated by the prompt use of amyl nitrite, we may well consider the propriety of an exsection of the cervical sympathetic.

Adenocarcinoma of the Male Breast.—Frank C. Hammond reviews the literature on this subject, and reports two cases. The first patient was a German, aged seventy-five years. There was no history of trauma and the family history was good. Pain was the prominent symptom. The tumor was removed and the pathological report was as follows: The specimen consists of an elliptical piece of skin, with subjoined tissue, 11.5 cm. by 6.5 cm. by 4 cm. In the center is a conical elevation 2.5 cm. above the level, and 4 cm. in diameter. On this is a nipple. It is 5 mm. in diameter and 3 mm. above the level. It is surrounded by a furrow 2 mm. in depth. There is a discolored area about the nipple. The skin is fixed to the tumor for about one-half of its extent. Portions of the new growth were traced to the extreme inner border of the specimen or line of incision. The second patient was a professional man, over fifty years of age. This tumor was in the right breast, while the one just described was in the left. The breast was excised. The specimen measured 3 by 2 by 2 cm. The surface was ragged. About one-half of the specimen was composed of what appeared to be adipose tissue. It was soft and spongy. The rest of the specimen was soft and firm and slightly resistant on incision. On examination the neoplasm was determined to be a glandular carcinoma. Although it was not rich in stroma, it might be termed a scirrhus. It was fairly circumscribed and with little evidence of peripheral infiltration.

Philadelphia Medical Journal, November 22, 1902.

Amputation through the Shoulder Joint as a Routine Procedure in Axillary Carcinoma, Secondary to Mammary Tumors.—John B. Roberts emphasizes these points in his interesting paper: Amputation through the shoulder joint should be adopted as a routine measure in all cases of axillary carcinoma, secondary to malignant disease of the breast, and the subclavian artery and vein should be ligated above the clavicle before the disarticulation is done. Then the arm should be cut off and the lymph nodes and other affected tissues removed. A flap from the outer aspect of the arm may be retained to cover the axilla and chest, if such integument is needed.

A Case of Exophthalmic Goiter Presenting Some Unusual Features.—Charles Potts reports this case. The patient was a man aged thirty-nine years. He is a miner. Aside from the excessive use of tobacco, his habits are good. He showed most of the usual symptoms of exophthalmic goiter. In addition, he had a marked ankle clonus. He has had a number of attacks of either partial or complete unconsciousness. He was placed on sodium phosphates, gr. xv, t. i. d. In a week he felt better. Treatment for a hypertrophic rhinitis, from which he had suffered for a long time, was begun; soon improvement became more marked. The case is interesting, especially from these facts: The patient is a man; the existence of an ankle clonus which was marked and not easily exhausted, and which disappeared as the patient improved; the occurrence of attacks of apparent unconsciousness; the marked improvement which followed the use of sodium phosphate, and especially the correction of disease of the nasal mucous membrane. The patient has had no treatment for nearly a year, but writes that he is feeling well.

The Lancet, November 15, 1902.

Death after the Removal of Tonsils and Adenoids in a Hæmophiliac Child.—F. J. Steward reports the case, the patient being a boy of seven years. Ether was given, and the usual operation performed. The growths were large. Bleeding was free at the time, but stopped spontaneously. When the patient was put back to bed it was noticed that the pulse was 160, and very feeble. Two hours later the pulse had improved, but it was noted that both sides of the neck, and also the left cheek, were swollen from blood extravasations. These swellings increased, and soon reached the sternum and clavicles. No further bleeding from the cut surfaces took place. Some eight hours later, dyspnœa developed, with submucous pharyngeal bleeding. The dyspnœa finally demanded intubation, but no relief followed. Tracheotomy was finally done, but death ensued thirty-two hours after the operation. The only abnormality found at the autopsy was a large thymus. No family history of hæmophilia could be obtained, but the author has no doubt that this was the real nature of the case.

Fatal Cerebral Hemorrhage in a Youth.—The patient of T. M. Pearce was a lad of nineteen, who, while washing himself suddenly felt a headache, and began to have a twitching of the right hand, and especially the thumb. Soon the twitching spread to the arm, and the patient lost consciousness. When seen a few minutes later by the physician, the pupil reflexes were lost—the right pupil was contracted, the breathing was labored and noisy; the pulse was 120 to the minute, but the heart sounds were normal. Convulsions continued, the head being drawn sideways, toward the right shoulder, the arms rotated inward, and there was pleurothotonos, with the concavity on the right side. Twenty minutes before death the body relaxed. Death ensued in about one hour from the initial seizure. Autopsy revealed a clot in the cerebral ventricles, more blood being in the left lateral ventricle than in its opposite on the right side. Bleeding had, apparently, commenced on the left side. There was no clot in the brain substance itself, nor could any ruptured vessels or miliary aneurysms be found. No cause for the attack could be ascertained. The young man was something of an athlete, but it does not appear that there had been any accident or over-exertion.

A Case of Tetanus Treated with Antitetanic Serum; Recovery.—W. E. Wynter reports the case of a man aged forty years, who ran a rusty nail into his foot. The latter began to swell, but he continued to work at intervals. In the course of nine days stiffness had developed. The incubation period, therefore, had been nine days, spasms occurring on the tenth day, counting that of the injury as the first. These spasms recurred during twenty-seven days, and forty-five days elapsed between the injury and complete convalescence. Fever was noted for fourteen days, the highest temperature being 102.6° F. on the eighth day from the appearance of symptoms. Antitetanic serum was given in doses of 10 cubic centimeters every six hours for sixty doses, until the spasms subsided. Extract of physostigma was administered in half-grain doses, also every six hours, and only omitted when all rigidity had gone. Morphine was relied upon to relieve the pain and to induce sleep during the acute period, but 2 grs. a day were never exceeded. Applications of hot water certainly relieved local spasm, and evacuation of the bowels was always attended with benefit. The urine was very constant in composition, though varying in quantity with the amount of perspiration. It was dark, but without deposit, it gave an acid reaction; it had a specific, gravity of 1028, and there were no abnormal constituentst such as blood, albumin, or sugar. The toxicity was not tested. It was on account of the concentrated character of the urine that rectal injections of hot water were resorted to.

British Medical Journal, November 15, 1902.

An Outbreak of Typhoid Fever, Waterborne. Jas. Taylor, medical officer of health of the Tandragee Dispensary, states that the first case of this epidemic was observed on July 7, and between that date and August 25, 225 cases were reported, extending over an area of about twenty-five square miles, all of which were subject to the influence of water proved by chemical and bacteriological analysis and circumstantial evidence to contain sewage matter and possibly enteric bacteria. Aside from cutting off the polluted water, the precautions taken to prevent the spread of the epidemic were: Removal of all patients fit for deportation to a hospital. Disinfection of fæces, soiled clothes, and premises in which cases occurred. Destruction of possibly infected refuse by fire. Structural improvements in water supplies and sewage system. The disinfectants used were carbolic acid and perchloride of mercury.

Epidemic Jaundice in South Africa.—R. V. Dolbey says that the symptoms of this disease are invariably consistent, and occur as follows: Patients will come at first complaining of loss of appetite, nausea, vomiting, and feelings of malaise, while there is always a history of constipation or diarrhœa. In many patients there is a temperature from 100° to 103°, while in malarial patients an attack of ague ushers in this disease. In a few hours great pain develops in the epigastrium and right hypochondriac region. The liver is enlarged, as is also the gall-bladder. The urine is generally dark and the stools white. Later the yellow discoloration of skin and conjunctivæ shows itself. The best treatment is rest in bed, milk diet, and calomel. The disease lasts from ten days to three weeks. The writer thinks that these are cases of obstructive jaundice caused by catarrh spreading up from the duodenum to the gall-bladder and liver.

A Case of General Pneumonic Infection in a Child of Seventeen Months.—Harold R. D. Spitta reports this case. The bacteriological report is as follows: The original pneumonia showed itself first on March 7. Next, the left elbow-joint was affected, and aspiration fluid showed the diplocccus pneumoniæ. On March 24 empyema declared itself with the same organism. The blood was examined on April 20, and the cerebrospinal fluid on April 24, and both showed this organism. Death occurred on April 28, and a partial necropsy was performed. Squeezings obtained from the solid areas in the lungs showed in cover-glass preparations very large numbers of typical lanceolate cocci. Coverslips, made from the fluid aspirated from the elbow-joint, presented a few capsulated cocci. The mother gave the history of a discharge from the ears for some time before the child's entrance to the hospital, but no ear trouble was ever observed in the hospital, although it was carefully looked for. The case is interesting from the presence of the multiple secondary infections.

Two Cases of Hyperpyrexia, with Recovery.—Robert E. Lord describes these cases. The first patient was a clergyman, thirty-two years old. He was of neurotic type and family. His illness was ushered in by a "bilious attack," with violent headache, pain in the legs, drenching sweats, and vomiting. His temperature was 101°. There were no symptoms or signs of throat, abdominal, or lung mischief. There had been an extensive periostitis, implicating a large part of the deltoid and biceps muscles some time before, and at this time there was present on the outer side of the humerus a hard, bony node. The case was considered influenzal, and an aperient and a diaphoretic were ordered. Within a few days the patient's condition became worse. He was delirious and sleepless at night and profoundly apathetic, lying under large quantities of bedclothes. There were no physical signs in any of his organs, no sugar, albumin, or diazo-reaction in the urine, and no alteration in the periosteal node. The spleen was not enlarged. On the sixth day he had a convulsion, and the axillary temperature corresponded to 111.5°. The thermometer was the next day certified at Kew to be correct to 0.2° up to 110°. Strychnine sulphate and a cold pack were given, the temperature dropping to 108°. After this he was put into a cold bath and kept there about forty five minutes. His temperature had then fallen to 101°. Between 5 P.M and 2 A.M on the next day seventeen excessively foul motions were passed. His temperature rose again to 104°. On the fourth day there had developed a mottled rash, and on the sixth day there was a very slight and doubtful enlargement of the spleen. On the seventh day he was better. From the ninth to the fifteenth day he was desperately ill. On the tenth day he began to peel. The after-progress was very slow, with alternate constipation and diarrhœa for weeks. The evening temperature did not reach normal till the forty-seventh day. Ultimately a good recovery, both physical and mental, was made. The diagnosis apparently lay between influenza, osteomyelitis or abscess of the humerus, typhoid, typhus, scarlet fever, and a septic condition of the alimentary canal. After consideration of all the symptoms and the course of the disease, influenza of an abdominal type or alimentary sepsis appear to be the most probable diagnoses, and will, in conjunction with the patient's neurotic family and history, and his excess of clothing during the earlier part of the illness, according to the writer's opinion, explain satisfactorily the main features of the case. The second patient was a soldier home from India with abscess of the liver. Although it had been drained, there were some pockets which gave rise to trouble, and one evening his temperature was found to be 110°. This was confirmed by the second thermometer. He died some months afterward from exhaustion. The only chance for such cases is the prompt abstraction of heat by means of an icepack or cold bath, and the exhibition of stimulants, of which a saline injection appears to be the best.

Deutsche medicinische Wochenschrift, October 30, 1902.

A New Kind of Diphtheria Serum.—A. Wassermann has succeeded in obtaining a bactericidal diphtheritic serum by inoculating rabbits and goats with diphtheria bacilli which have been treated by a method similar to that first used by Koch in the preparation of tubercle bacilli for the production of tuberculin. The serum thus obtained is not only bactericidal, but possesses specific agglutinating and precipitating properties. On account of the latter, it is thought that its chief use is to be found in the differentiation of pseudo- and true diphtheria bacilli. It may, however, find a field for clinical use in those cases in which the bacilli persist in the throat for a considerable period after all symptoms have disappeared. Such cases are, as a rule, not under quarantine, and are important factors in the spread of the disease. In such patients, after inoculation with a bactericidal serum, there should be a rapid disappearance of the bacilli.

Acute Syphilitic Nephritis.—Waldvogel reports a case which exemplifies this condition and adds further evidence to the view that the syphilitic poison may give rise to a true nephritis. The patient had previously passed through measles and pneumonia, but following these diseases had remained in good health until he developed syphilis. At the time of the first examination condylomata and specific throat lesions were present. Shortly thereafter œdema of the lower extremities, ascites, and hydrothorax developed. The urine contains both albumin and casts. Under the administration of mercury the œdema subsided and the albumin and casts gradually disappeared from the urine. The diagnosis of syphilitic nephritis was made upon the simultaneous appearance of the nephritic and syphilitic symptoms and the disappearance of the former under the administration of mercury.

Origin of the Basophilic Granules in the Red Blood Cells.—P. Schmidt thinks that the basophilic granules frequently encountered in red blood cells are remnants of a broken-up nucleus, and that when a fair number of erythrocytes contain them it means that an active regeneration of these cells is taking place. Recent observations by the author upon a case of malarial anæmia confirm this view. When the case was first seen the erythrocytes were very much reduced below their normal number and contained few, if any, basophilic granules. Under treatment the number of erythrocytes markedly increased, and eventually nearly normal figures were obtained. During the stage of active increase of the erythrocytes the basophilic granules became numerous, and so remained until the regeneration had taken place, when they again became scarce. Observations upon the blood in anæmias of other origin give the same result, and there seems to be no doubt but that the presence of the granules signifies regeneration rather than degeneration of the erythrocytes, as has been claimed by several authors.

The Significance of the Presence of Typhoid Bacilli in the Sputum in Acute Pulmonary Affections Complicating

or Following Typhoid Fever.—Felix Glaser does not think that the presence of typhoid bacilli in the sputum or pulmonary tissues in acute pulmonary affections complicating or following typhoid fever necessarily means that these organisms were the primary cause of the lung trouble. This view is based upon the observation of two cases of lobar pneumonia complicating typhoid fever, in both of which typhoid bacilli were present in the sputum, and in one of which they were also obtained from the consolidated lung by puncture. In both cases, however, there were pneumococci present in the sputum, which were highly virulent for animals. Certainly, so far as the pulmonary condition is concerned in this class of cases, the lesions must be considered as due to a mixed infection of pneumococci and typhoid bacilli. It cannot be denied that there are cases of lobar or lobular pneumonia due solely to the typhoid bacillus, and in which no pneumococci can be found, but it is nevertheless certain that the mere presence of the typhoid bacillus in the sputum does not necessarily mean that the pulmonary lesion is essentially typhoid in character.

Münchener medicinische Wochenschrift, November 4, 1902.

New Method for the Diagnosis of Lung Cavities.—H. Cybulski says that in lung cavities the adventitious sounds which are heard on ordinary auscultation may also be distinctly heard if the ear of the examiner is placed close to the wide open mouth of the patient, while the latter practises deep inspirations and expirations. This method of diagnosis is especially valuable in that class of cases in which, upon ordinary auscultation, the cavity signs are obscured because of other lesions in the surrounding pulmonary tissue.

Pleural Effusions in Cardiac Diseases.—Jos. Esser reports three cases which throw some light upon the pathogenesis of this condition. In all three cases myocarditis was the cardiac lesion. In all the pleural effusion was principally, if not entirely, right-sided. At autopsy, the bronchial gland on the right side at the hilus of the lung were enlarged and more or less calcified in all. As in these cases, many other observers have also shown that pleural effusions accompanying cardiac lesions are much more frequent when the myocardium is involved than when the valves alone are affected; this is to be ascribed to the inability of the heart muscle to maintain the normal circulatory power, by reason of which a venous congestion takes place. The cause of the more frequent of such pleural effusions on the right side is to be sought in the anatomical constructions of the bronchial lymphatic system on that side. As is well known, on that side the efferent vessels from the bronchial glands of the hilus empty into the truncus bronchomediastinus, the same vessel which receives the efferent vessels from the pleural cavity, which is, of course, to be regarded as a lymphatic space. Hence, any cause which leads to a congestion of the lymph in these glands and their efferent vessels would favor the development of a pleural effusion. As above said, such a cause is to be found in an incompetent cardiac muscle.

French and Italian Journals.

Nocturnal Incontinence of Urine; Treatment by Instillations of Nitrate of Silver.—Clément Delfosse reviews a number of cases of incontinence. He has had great success in treating them with instillations of nitrate of silver. After washing the anterior urethra, he instilled into the posterior urethra from fifteen to twenty drops of the solution of silver nitrate, one to thirty. After the first treatment three patients were cured; after the second, one; after the third, one more. The condition of two others was ameliorated. All of the patients have been examined several months after their cure. It is difficult to explain the method of action of this drug, and although several interesting hypotheses are suggested, they are, after all, only hypotheses.—*Journal des Sciences Médicales de Lille*, November 1, 1902.

Suppurating Calculous Cholecystitis.—Barnsby saw a patient upon whom he was called to operate *in extremis*. The general condition was very grave. The patient presented a large tumor, perceptible on palpation, plainly fluctuating, occupying the right iliac fossa, separated from the liver by a sonorous zone, and not accompanying this organ when it was displaced. The patient had never had any functional symptom on the part of the bile passages, but had shown all the train of gastrointestinal troubles. The diagnosis was made of "periappendicular abscess," with a reservation in favor of suppurating cholecystitis, on account of a very sharp pain, provoked by palpation under the inferior surface of the liver. Operation showed a distended gall-bladder, adherent to the cæcum and ascending colon. Seven hundred grams of pus and 294 small calculi were obtained. Cholecystostomy was performed. Recovery was rapid.—*Gazette des Hôpitaux*, November 6, 1902.

Endovenous Therapy.—F. Mariani concludes from his researches that oxygen injected into the veins is completely absorbed by the red corpuscles, and does not cause emboli. The injection must be performed slowly, not more than 500 c.c. of oxygen being injected in an hour, in order that it may all be absorbed. This administration of oxygen is valuable in all cases of pneumatosis. Intravenous injections of therapeutic doses of corrosive sublimate effect no change in the red nor in the white corpuscles, the amount of hæmoglobin remains the same, and there is no especial modification of the isotonia of the blood. Preparations of iron, of arsenic, iodine, alcohol, gelatin, silver nitrate, and other drugs can be injected intravenously with benefit in certain conditions. This method of medication constantly receives further substantiation from investigators, and redounds to the credit of its discoverer, Guido Baccelli.—*La Riforma Medica*, November 3, 1902.

Latent Cancer of the Stomach with Numerous Metastases.—M. A. David describes this case. The patient was a man of fifty-eight years. He was first brought under observation for the treatment of erysipelas, but he presented, at the same time, grave general phenomena. But there was not the least gastric symptom. Later, there developed a little œdema of the limbs, which lasted only a few days. He soon after left the hospital, in apparently excellent condition. He never complained of pain in the stomach, nor of vomiting, nor of melæna. He returned some weeks later complaining of vague malaise. He was cachectic. There was a hard mass in the epigastric region, but its form and connections could not be made out. Supraclavicular ganglia could be felt. The diagnosis of neoplasm of the stomach was made. The patient died the next day, after having had some melæna. Autopsy revealed an encephaloid cancer in the cardiac portion of the stomach.—*Journal des Sciences Médicales de Lille*, November 1, 1902.

Traumatic Rupture of the Spleen.—Giovanni Ninni reports the case of a boy of sixteen years who had been kicked by a horse in the left abdominal region. The extreme pallor of the patient, the filiform, and almost imperceptible pulse, the great tension of the abdominal walls, and the fact that there had been an escape of blood from the anus, prevented all hesitation in regard to laparotomy. Abundant hemorrhage followed incision, and was seen to have its source in a large laceration of the spleen. The patient's condition, in spite of injections of ether and of caffeine, became so alarming that the operator was obliged to arrest hemorrhage by an extensive gauze tampon. An intravenous injection of 1,700 grams of normal salt solution was then given, which had the effect of miraculously resuscitating the patient. The postoperative course was absolutely satisfactory; there was no temperature, nor the faintest sign of secondary hemorrhage, not even when, on the sixth day after operation, the plug of gauze was removed. In a month's time, the patient left the hospital entirely cured.—*Giornale Internazionale delle Scienze Mediche*, October, 1902.

Nervous Crises Consecutive to Ablation of the Adnexa, Cured by Gynecological Massage.—Cécile Seder reports this case. Her patient was a woman of thirty-four years, who had undergone, seven years before, a double ovariotomy. She suffered from actual nervous crises. The patient did not know what provoked them. The crisis began with acute pain in the region of the adnexa, especially on the right side; it extended up as far as the waist. There was distension of the abdomen and vomiting. The patient was unable to take any nourishment. These sever symptoms lasted one or two days. Finally, the pain subsided, and the symptoms disappeared, but the digestion remained disturbed for some time. The last crises were very severe, and so weakened the patient that she had to keep her bed for two or three weeks. Massage was begun. Nothing was noticeable in the region of the removed organs, only a clammy feeling and a rigidity of the tissue, a little more on the right side. The abdomen was rather hard. The uterus was infantile. The vagina was in a condition of irritation. The course of massage was continued; the clamminess vanished and the tissues became pliable. The patient felt a little local pain scarcely two or three times in six months. The massage proved to be of great value, both locally and generally.—*Journal de Médecine de Paris*, November 2, 1902.

The American Journal of the Medical Sciences, October, 1902.

Infection of Ovarian Cysts During Typhoid Fever; Report of Two Cases; Operation; Relapse; Recovery.—Morris J. Lewis and Robert G. Le Conte present this paper. The condition considered is a rare one. The first patient was a woman of twenty-eight years, who was admitted to the hospital with a temperature of 104.8° F., pulse 120, and respiration 32. Five weeks before admission she had given birth to a full-term child. She was admitted under the diagnosis of puerperal sepsis, but within a few days it was evident that the illness was typhoid fever. When convalescence should have been established, the fever did not touch normal, but assumed a hectic character, with coincident abdominal pain and enlargement. The leucocytes, which had previously been subnormal, doubled in number. A vaginal examination revealed a large, exquisitely tender, fluctuating mass in Douglas' cul-de-sac, which bulged in the posterior wall of the vagina and pushed the uterus up behind the pubis. The cyst was estimated to contain from one to two pints of pus. A blood count showed 10,400 leucocytes, with 55 per cent. of hæmoglobin. The patient finally agreed to a vaginal puncture of the abscess, and about a quart of fetid pus, with many cheesy particles, was evacuated. The diagnosis of teratomatous cyst was assured. There was also cartilage and bone in the cyst wall. During the next week the temperature gradually rose to 104.4° F. This rise was continuous and not hectic. There proved to be a relapse, for the leucocytes returned to a subnormal number, the spleen again became palpable, and a new crop of rose spots appeared. The pus that had been evacuated showed large numbers of the bacillus typhosus. Later the diseased ovary, together with the tube, was removed through an abdominal incision.

The Theory of Cross Education as Applied to the Auditory Apparatus.—Lewis S. Somers reports certain experiments which he made upon the auditory apparatus to determine what effects mechanical movements of the membrana tympani and of the chain of ossicles would have upon the hearing-power of the opposite ear. The writer states that the cases selected were those in which the hearing was defective from sclerotic changes in the conducting apparatus, but in which the perceptive portions were, as far as ascertainable by recognized tests, not involved in the essentially chronic process. The method used in determining the effect of exercise of one ear upon the opposite one was to make the usual tests of hearing of both ears, the voice, watch, and tuning-fork being used for this purpose. Movements of the membrana tympani and ossicular chain were made by rarefying and condensing the column of air in the external auditory canal by means of a ten-ounce Politzer bag and a Siegle otoscope tightly fitted into the canal. In one of these cases, in the right ear the hearing increased from nothing for the watch to a fair hearing distance of three inches, while in the left, non-exercised ear, the hearing for the watch, which was originally only on contact, had increased to two and one-fourth inches, a most remarkable gain, and one which clearly demonstrates the effects of cross education upon the auditory apparatus. The gain in hearing for the voice was shown in both ears.

Report of a Case of Severe, Probably Pernicious, Anæmia, with Marked General and Coronary Atheroma, in Which Many Evidences of Aneurysm Were Present without Anatomical Explanation for Them.—Arthur R. Edwards reports this case, which presents no remarkable pathological features. The vascular changes were very marked for a person aged thirty-one years, and may be referred with some degree of correctness to syphilis. The chief clinical interest of the case centers in the pulsation. Over the left lower chest was observed a diffuse and most distinct pulsation, which, as the patient lay on his right side, extended horizontally from the lower angle of the left scapula around the chest into Traube's space, and the epigastrium, and in a downward direction to a point distinctly below the left costal arch. The pulsation was vigorous and distinctly expansile to both the eye and hand. A systolic bruit was heard over the pulsating area, but was most clearly audible over the left chest behind. No thrill was detected at any time. The case was thought to be one of aneurysm. Post-mortem revealed nowhere any bulgings or aneurysm of the aorta. No satisfactory explanation of the pulsation noted has been reached. There was partial left adhesive pleuritis, and the active arterial pulsation might have been propagated by means of the adhesions to the chest and by means of the perisplenitic connective tissue to the abdomen. But this suspicion, as the writer says, in no way accounts for the expansile character of the pulsation, which of yore has been held to invariably exclude dynamic pulsation. Lafleur recounted a case in which the pulsation was exactly similar to that of this case. It was expansile, but instead of aneurysm, the autopsy showed gastric ulcer.

A Case of Acute Lymphatic Leukæmia without Enlargement of the Lymph Glands.—Dorothy M. Reed reports this case, the important points of which are that, in a sudden and rapidly fatal illness, in which there were no especial features other than hemorrhage, anæmia, and a marked increasing weakness, there was present the blood picture of an intense lymphocytosis, establishing thus the diagnosis of acute lymphatic leukæmia. There was no enlargement of either lymph glands or spleen. But the bone marrow showed macroscopically the features of lymphadenoid degeneration. The writer believes that the findings in this case prove conclusively that there is here a lymphocytosis arising from proliferation of lymphoid cells in the bone marrow, and death occurring before any other organ in the body showed involvement. Although it cannot be stated positively that the lymphocyte of the blood comes from the bone marrow, still there is no proof that the lymphocyte comes from the lymph gland alone, and that all the other colorless cells of the adult blood originate in the bone marrow from lymphoid cells. In this case the similarity in form of the small lymphoid cells with the normoblasts, which were conspicuously few in number, was suggestive. It is not impossible that the increase here was in a mother cell, from which the lymphoid cell and the hæmoglobin-containing cell are normally derived. The writer believes that such cases go to prove that acute leukæmia, whether lymphoid or myelocytic, is due to changes in the bone marrow, the other hæmopoetic organs being involved, if at all, secondarily. She suggests that there are three forms of leukæmia, all due to myelogenous changes, and that these should be known as the myelocytic, lymphoid, and mixed-cell varieties, if we wish to make the blood-picture the bases for clinical divisions.

Malaria: a Summary of Recent Progress in the Knowledge of Its Etiology and Prophylaxis.—Barton Lisle Wright states that it is now a certain and generally accepted fact that malaria is produced by the bite of an infected mosquito of the genus Anopheles. The following sanitary measures should be adopted and put in force: (1) All hollows within the city limits, and for a mile surrounding it, should be filled in and graded. (2) Marsh lands within the same territory should be properly drained, and, where practicable, filled in. (3) Ponds and streams that cannot be drained or filled in should have their surfaces covered with petroleum, which should be renewed every twenty-one days. (4) Where for any reason this is impossible, fish should be introduced, so that they may feed upon the larvæ. (5) All receptacles holding water should be made mosquito-proof, or, where this is impossible, the surface covered with petroleum. If this water be drawn, by means of a faucet, from the bottom of the cask or tank, and not dipped out, it will not be unfitted for drinking or washing purposes. (6) Old cans and pans exposed so that they might collect rain water should be carefully covered. (7) Householders should be advised to thoroughly screen their houses. (8) Thoroughly-screened isolation wards should be provided in the hospitals. (9) All cases of malarial fever should be reported to the Board of Health, the same as other infectious and contagious diseases. (10) Where the patient cannot be properly isolated at home, he should be removed to the hospital. (11) The sick room should be thoroughly screened, completely isolating it from other parts of the house, as well as from the outside. (12) The mosquitos in the other rooms should be carefully destroyed. (13) When the plasmodium has disappeared from the blood, the patient should be removed to another room, and the mosquitos in the sick room destroyed by fumigation. (14) Cesspools should have their surfaces covered with petroleum at least once a week.

The Pathology of Pernicious Anæmia, with Special Reference to Changes Occurring in the Hæmolymph Nodes (Eight Autopsy Cases).—Alfred Scott Warthin concludes that: (1) Pernicious anæmia is essentially a hæmolytic disease, the hæmolysis being due to some as yet unknown poison, comparable in its effects upon the blood and blood organs to the action of toluylenediamine—whether auto-intoxication or infection, remains yet to be determined. (2) The poison of pernicious anæmia stimulates the phagocytes of the spleen, lymph and hæmolymph glands, and bone marrow to increased hæmolysis (cellular hæmolysis). Either the phagocytes are directly stimulated to increased destruction of red cells, or the latter are so changed by the poison that they themselves stimulate the phagocytes. The hæmolysis of pernicious anæmia differs only in degree, not in kind, from normal hæmolysis, or the pathological increase occurring in sepsis, typhoid, etc. (3) It is not improbable that from the destruction of hæmoglobin poisonous products (histon?) may be formed which have also a hæmolytic action—a vicious circle of hæmolysis may thus be produced. No proof of this exists at present. (4) The hæmolysis of pernicious anæmia is not confined to the portal area, as, according to Hunter, but in some cases at least takes place also, to a large extent, in the prevertebral lymph and hæmolymph nodes and bone marrow. In the majority of cases the spleen is the chief seat of the blood destruction. No evidences of hæmolysis in the liver, stomach, and intestinal capillaries were found in the eight cases. The hæmosiderin of the liver and kidneys is carried to these organs as some soluble derivative of hæmoglobin, is removed from the circulation as hæmosiderin by the endothelium, and then transferred to the liver or kidney cells. The deposit of iron in these organs is of the nature of an excretion. (5) In the majority of cases only slight reaction for iron is found at the sites of actual hæmolysis (spleen, lymph and hæmolymph glands, and bone marrow). The greater part of the pigment in the phagocytes of the spleen, lymph, and hæmolymph glands does not give an iron reaction while in a diffuse form. When changed to a granular pigment, the iron reaction may usually be obtained. The change to hæmosiderin is for the greater part accomplished by the endothelium of the liver and kidneys. (6) The varying pathological conditions found in these different cases of pernicious anæmia can be explained only by a theory of cyclical or intermittent process of hæmolysis. This theory is also borne out by the exacerbations so frequently seen clinically. The autopsy findings, in so far as evidences of hæmolysis are concerned, will depend upon the relation between the time of death and the stage of the hæmolysis. (7) The changes in the hæmolymph glands found constantly in these eight cases were: dilatation of the blood sinuses and evidences of increased hæmolysis, as shown by the increased number of phagocytes containing disintegrating red cells and blood pigment. In some of the cases these changes were accompanied by great increase in size, and apparent increase in number, of the hæmolymph glands; in other cases there was no hyperplasia, the only evidence of the changes present being that obtained by the microscopic examination. The changes found cannot be regarded as specific of pernicious anæmia, since it is probable that they may be produced by other infections or toxic processes characterized by great hæmolysis. (8) The lymphoid and megaloblastic changes in the bone marrow do not form an essential part of the pathology of pernicious anæmia, and are to be regarded as of a compensatory nature—an increased activity of red cell formation to supply the deficiency caused by the excessive hæmolysis.

Book Reviews.

International Clinics: a Quarterly of Illustrated Clinical Lectures, etc. Edited by Henry W. Cattell, A.M., M.D., and Various Collaborators. Volume II, Twelfth Series, 1902. Philadelphia: J. B. Lippincott Company, 1902.

No less than twenty-seven well-known writers have aided in making this volume the attractive one it is. Such names as Lépine, Finger, Robin, Lucas-Championniere, Pick, Patton, and Hemmeter are among those who contributed The volume is freely illustrated. Professor Senn has a valuable surgical article, including a great variety of every-day, as well as some unusual, conditions. Resection of the cervical sympathetic is attractively discussed by Professor Jonnesco. The work is being well kept up to its standard.

Traité de Médecine et de Thérapeutique. Publié sous la direction de P. Brouardel, Doyen honoraire, Professor à la faculté de médecine de Paris, Membre de l'Institut, et A. Gilbert, Professor de thérapeutique à la Faculté de Médecine de Paris. Médecin de l'Hôpital Broussais. Tome Neuvieme. Paris: J. B. Baillière et Fils, 1902.

This ninth volume of Brouardel and Gilbert's important work on practice and therapy treats upon diseases of the brain and its meninges; the spine and spinal meninges; The contributors are. Bourneville, Raymond, Claude Hutinel, Klippel, Déjerine, Thomas, Gilbert, and Lion. The volume is well though sparsely, illustrated, both from the clinical and pathological side The various diseases of the nervous system have been carefully and elaborately worked out.

The system, of which these 1,000 pages form part, maintains its elevated standard as the set is nearing completion, and when completed it will be an almost necessary addition to all important medical libraries. French-reading physicians will find in the work all subjects treated from a modern scientific and serious point of view.

Smallpox Illustrated. By George Henry Fox, A.M., M.D., with the Collaboration of S. D. Hubbard, M.D., S. Pollitzer, M.D., and J. H. Huddleston, M.D. Philadelphia and London: J. B. Lippincott Company, 1902.

This Atlas, in two parts, corresponding to the larger atlas of skin diseases by the same author, is a practical treatise illustrated by colored photographs from life The pictures are extremely well-executed and show variola erythematosa on the first day, variola papulosa (second day), variola hemorrhagica, variola vesiculosa (fourth day), variola of mixed type, semi-confluens, confluens and pustulosa (ninth day). In part II there are eight illustrations: variola discreta, pustulosa, crustosa, mixed forms, variola desiccata et squamosa, pigmentations. hypertrophic scars, etc. In the last plate vaccination with its varieties and complications is depicted.

Taken as a whole, the small atlas, with its descriptive text, can be regarded as the most finished work of the kind that has yet appeared.

Diagnostic Gynécologique des Organes Génitaux et de la Mamelle. Par le Docteur Clado, Chef des Travaux de Gynécologie a l'Hôtel-Dieu, Ancien Chef de Clinique de la Faculté. Paris: A. Maloine, 1902.

This book of 800 pages presents a broad view of the subject treated. The volume is divided into three sections. The writer presents this arrangement: The first part is a detailed description of the various methods which are of use in the diagnosis of gynecological affections. The second part comprises the study of the diagnosis of genital affections and the general phenomena to which they give place. This section treats of the diagnosis of the affections of the vulva—traumatic affections, those due to microbic origin, tumors, tuberculosis, pruritus, etc.—affections of the vagina, cervix, fundus, uterine adnexa, and peri-uterine affections; tumors of the round ligament; and extra-uterine pregnancy. The third section treats of the affections of the breast. The text is embellished with numerous illustrations from nature by the eminent artists Henri Cain and Théo. Ralli. The most modern methods of diagnosis are described and the mechanical arrangement of the text is very clear. The volume is a very convenient book of reference for the practitioner and shows wide research. The name of the author is a sufficient gurantee for the excellence of this work.

La Guérison de la Morphomanie sans Souffrance. Par le Dr. Oscar Jennings. Traduit de l'anglais par M. Albert Ball. Paris: A. Maloine, 1902.

The second edition of this little volume, which recommends essentially the same treatment that the author has been using for ten years, nevertheless, presents certain variations from the original edition. Some of the chapters have been revised and new ones have been inserted. Personal letters concerning the treatment are printed, which serve to bring the subject most vividly before the reader. All care is taken that the patients may avoid suffering during the treatment. The drug is gradually reduced, and is finally given by rectal injections. Appropriate medication is made use of, and a very prudent and non-alcoholic régime is observed.

A Text-Book of Medicine. Begun by the late Charles Hilton Fagge, M.D., F.R.C.P., sometime Physician to Guy's Hospital. Completed after his death and since Revised or Rewritten by Philip Henry Pye-Smith, M.D., F.R.S., Fellow of the Royal College of Physicians; Consulting Physician to Guy's Hospital. Fourth Edition. In Two Volumes. Vol. II. Philadelphia: P. Blakiston's Son & Co, 1902.

The present volume is the second and last, its predecessor having appeared about a year ago. It comprises practically all the subjects which were not included in Volume I, continuing the diseases of the lungs and presenting the diseases of the heart, pericardium, aorta, mouth, œsophagus, stomach and intestines, liver, kidneys, blood, and skin, as well as those affections not easily classified. Dr. Pye-Smith is really responsible for the text, although he has drawn upon his associates' work very largely. The work is somewhat different from the usual textbook, in the fact that the personal experiences of the authors give an individuality to the subject matter, which is not always present in these days of specialism. The brief references to certain cases which serve to bring out illustrative instances give a brightness to the text which would otherwise not exist. The historical references are unusually full, and due credit for discoveries is always given to the famous observers of the past. Perhaps the clinical pictures of the diseases described merit most of the praise, they are graphic and comprehensive. The treatment and diagnosis sections are always good, although, purposely, not exhaustive. In the article on Typhlitis the stand regarding non-operative interference will seem too strong to American teachers, while the almost wholesale condemnation of morphine in Bright's disease will meet with the disapproval of those clinicians who so strongly favor its use in uræmic convulsions with high arterial tension. The chapters on dermatology are unusually comprehensive, over two hundred closely printed pages having been assigned to this specialty. The two volumes may be considered a valuable addition to the library of the medical student and practitioners;

a trustworthy and helpful guide when they wish the counsel of experienced advisers. This new edition shows much improvement over the last, and has been brought thoroughly up to date, rearranged, pruned, and expanded, as seemed wisest to the author.

Beiträge zur Syphilis-Forschung, Von Dr. Max von Niessen. Parts VI and VII. Wiesbaden, 1902.

These contributions to the study of syphilis have more than a passing interest. There are related no less than seventy additional cases of syphilis in which the bacillus has been found in the blood. These are followed by tracing the subsequent history of the disease in the attempts at inoculation which the author has carried out in lower animals. There are ten half-tone full-page plates illustrating the effects of inoculation, the histological appearances, etc. The work abounds in interest to all who labor in this field. It is conveniently printed in both German and French, in parallel columns

A Manual of Practical Medical Electricity. The Rontgen Rays and Finsen Light. By Dawson Turner, B.A., M.D., F.R.C.P.Ed., M.R.C.P., London. Third edition. Revised and enlarged. New York: Wm. Wood & Company, 1902.

The increasing interest in that feature of electricity which pertains to the production of *x*-rays makes a third edition of this work, taking up as it does this new branch, doubly interesting. The earlier portions of the book have been revised and brought up to date, and the chapters on electrotherapeutics have been added to, especially as regards electrolysis. Forty-seven pages are given over to Röntgen rays, including may full-page illustrations, while twenty-four pages include all that the author has to say about *x*-ray therapeutics and Finsen light. What is said, however, is to the point, and the results of considerable personal experimentation with apparatus is given. The work evidently went to press before much had come out concerning treatment. The inconveniences of the Finsen method are made especially prominent, as they should be, and the Lortet and Genoud lamp is considered a step in advance, and this, it is thought, would give better results if fitted with iron-electrodes. As an aid to the study of electrotherapeutics in general, the work fills a decided place of utility.

Treatise on Diseases of the Skin, for the Use of Advanced Students and Practitioners. By Henry W. Stelwagon, M.D., Ph. D., Clinical Professor of Dermatology in the Jefferson Medical College and Woman's Medical College, Philadelphia; Dermatologist in the Howard and Philadelphia Hospitals; Member of the American Dermatological Association; Socio corrispondente di la Societa Italiano di Dermatologia e Sifilografia, etc. Philadelphia and London: W. B. Saunders & Company, 1902.

This handsomely-bound octavo of 1,125 pages is profusely illustrated, and the text, which is well written, reflects the author's large and varied experience. There is too much of the book for the purposes of the student, and, if such a thing is possible in a work on skin diseases, there are too many pictures. By this we mean, that too great prominence is given to the rare forms which the student is never expected to see during his course, and, in all probability, will never see during his practice. The same space might better be taken up as regards a number of the twenty-six full-page lithographs and plates by a series of every-day conditions in the manifold varieties in which they are encountered. In general scope and make-up the work does not differ materially from those published by teachers in other cities, but since dermatology is advancing in several directions it contains many observations and views not found in some of the less-recent textbooks. The work is so constructed with notes and references that it will prove of material value to the dermatologist as well as the general practitioner, student, and writer, and, one can feel confident that the literature of the past quarter of a century has been well sifted. In this latter work the author has had the aid of several well-known gentlemen in his city.

A System of Physiologic Therapeutics Edited by Solomon Solis Cohen, A.M., M.D., Professor of Medicine and Therapeutics in the Philadelphia Polyclinic, etc. Vol. IX. Hydrotherapy, Thermotherapy, Heliotherapy, and Phototherapy. By Wilhelm Winternitz, Professor of Clinical Medicine in the University of Vienna. Balneology and Climatotherapy. By Dr. E. Heinrich Kisch, Professor in the University of Prague, Philadelphia: P Bakiston's Son & Company, 1902.

These two works are translated by Dr. Augustus A Eshner, and combined with notes on American Springs by Guy Hinsdale; a Classification of American Waters by A. C Peale, Phototherapy and Thermotherapy, by J H Kellogg, and Saline Irrigation and Infusion, by Harvey Cushing Thus the work is not wholly foreign A short illustrated appendix has also been added by the editor. Altogether there are 570 pages, making a considerably larger volume than those of the series first published.

The work is thoroughly in keeping with the spirit of the times in making the most of all physical means of treatment, and not relying wholly upon drug medication Many of the plans of treatment here scientifically placed before us are those formerly in use by the few, or, possibly, only by those looked upon as irregular practitioners. Much, however, is relatively new, but the newest therapeutical measure of all—that by the *x*-ray—is, strangely enough, mentioned but once, on page 50

All that pertains to treatment by water, both internal and external, has been discussed from various standpoints by different writers. This part is well illustrated, showing how to give the various baths, apply sheets, use hot-air cabinet, put on packs, employ incandescent lamps for electric-light baths, etc. European and American thermal and medicated baths are well described, with their effects upon various diseases The volume would be more readable if it were less bulky, and the material might have been somewhat concentrated with this in view It is hand-book size, but too heavy to hold in the hand. The Finsen light and apparatus are described and illustrated, but the details of actual results are scant, and little aid is given the searcher for information as to how he can himself apply the method. Aside from these faults, the work is highly commendable.

Disinfection and Disinfectants. A Practical Guide for Sanitarians, Health and Quarantine Officers By M. J. Rosenau, M D., Director of the Hygiene Laboratory, and Passed Assistant Surgeon, U. S. Public Health and Marine Hospital Service, Washington, D. C. Philadelphia: P. Blakiston's Son & Company, 1902.

The author shows himself well qualified as a teacher of practical matters pertaining to health, both public and private. Not only are the plans and machinery for wholesale disinfection in quarantine and other service portrayed and well illustrated, but the details of avoiding communicable disease, disinfection of rooms, persons, and clothing, are presented in a simple and attractive manner, so that the lay sanitarian as well as the physician can grasp the whole situation. The publisher has done his work well.

Materia Medica, Therapeutics, Medical Pharmacy, Prescription Writing, and Medical Latin. By William Scheiff, Ph G., M.D., Instructor in Pharmacy in the University of Pennsylvania Second edition, revised and enlarged. Philadelphia and New York: Lea Brothers & Co., 1902.

This is one of the series of "pocket textbooks," edited by Bern B. Gallaudet, M.D , of New York. It was originally a very useful and attractive book, thought too large for the ordinary pocket, and in revision it has been improved. The title tells almost all there is in it, aside from a therapeutic index of new remedies, a table of doses, and a good therapeutical index apart from the general one. It is naturally intended only as a reference work and adjunct to the students larger textbooks.

Manuel d'Histologie Pathologique. Par V. Cornil et L. Rauvier, avec la Collaboration de MM A. Brault et M. Letulle. Troisième édition. Tome second. Paris: Félix Alcan, 1902.

This second volume of Cornil and Rauvier's excellent work on pathological histology contains the pathological anatomy of muscles by Durante; that of the blood by Jolly; of the blood and spinal marrow by Dominici, and that of the central nervous system by Gombault and Philippe. There are over two hundred black and colored prints in the text. This work needs little praise The well-known writers and editors sufficiently recommend it. The 856 pages of this volume represent a great amount of faithful investigation and research. The minute instruction in technique are alone worth the price of the volume The reproductions in color, of differentiation stains, is an attractive feature

Phonographic Outlines of Medical Terms, with an Appendix Third edition London: Sir I Pitman & Sons, 1902.

This little dictionary of medical phonography, issued by the Society of Medical Phonographers in Great Britain, should be of great utility to the young stenographer in assisting him to acquire a stock of easily-made and easily-remembered outlines The book contains a list of outlines and contractions for about three thousand of the more common medical terms.

Society Reports.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Proceedings of the Fifteenth Annual Meeting, Held in Cincinnati, Ohio, November 11, 12, *and* 13, 1902.

The association met at the Grand Hotel, under the presidency of Dr. W. E. B. Davis of Birmingham, Ala.

Hypertrophy of the Prostate.—Dr. N. P. Dandridge of Cincinnati, Ohio, read a paper on this subject. A case reported by him showed that complete perineal prostatectomy enabled the surgeon to deal with a class of most distressing cases in a more satisfactory way than ever before—cases which had remained rebellious to other methods. The author did not decry the merits of any of the newer operations upon the prostate, whether they be Bottini's operation or prostatectomy. He was convinced that the field of usefulness for the latter operation, when used with discrimination, was quite large. He urged strongly the necessity of not being carried away by operative furor, which might lead to the same excess which a few years ago characterized the surgery of the ovary, an excess which was now followed by a marked recoil. The experience of Murphy was worthy of special notice; namely, the ready manner in which stone in the bladder could be dealt with after a perineal prostatectomy. The necessary opening of the urethra afforded an opportunity for the extraction of stone.

Conservative Operations upon the Ovary.—Dr. L. H. Dunning of Indianapolis, Ind., in a paper on this subject, reported his experience with more than one hundred cases operated upon by himself. He employed the method of incising small single cysts, removing the lining membrane, trimming away the redundant portion of the outer wall of the cyst and joining the edges of the incision by a running stitch of fine catgut. Single hæmatoma was treated in a similar manner. In a few instances he had used the thermocautery to check hemorrhage, and in other instances he had punctured several small cysts and dropped the ovary. He reported gratifying results in 80 per cent. of cases. After a few trials he rejected conservative methods in pus cases, and in cases in which there were numerous small cysts in all parts of the ovary. He found conservative work unsatisfactory in sterile married women, and in interval appendicitis operations in which there was a markedly cystic right ovary. In his series there were known to be six cases of pregnancy in which the patients were happy mothers, and there was a group of ten cases in girls and young women from whom he had extirpated an ovarian tumor from one side, and had done a conservative operation upon the other ovary with a large measure of success. Even should a considerable per cent. of failures to cure appear, the writer would continue to do conservative work. He believed that the reason we were not able to select our cases was that cystic degeneration of the ovary was a progressive disease, the limits of which we were not able at present to predict. The hope was that with increasing knowledge we would be better able to select the curable cases for operation.

Dr. George H. Noble had done considerable conservative work on ovaries in such cases as the author had mentioned, and he was satisfied that it was the proper thing to do. He endorsed the paper *in toto*.

Dr. Henry T. Byford said that formerly ovaries were removed extensively by gynecologists, and that now there was a sufficient number of cases on record to determine what effect the removal of the ovaries had on young people. He recalled a number of patients from whom he had removed the ovaries, the operation having produced no harm or mental effect. In many of the cases the women had been in better health since the operation. Conservative operations, if aseptically and properly done, should be followed by good results, without necessarily removing the ovaries.

Dr. Walter P. Manton began conservative work on the ovaries several years ago, and had found in the majority of instances he was successful in relieving the symptoms. He had, however, had a few unsuccessful cases which led him to be skeptical in regard to the good work which he might have done formerly. A short time ago he removed the left appendages and resected the right ovary, the patient making an excellent recovery. He removed about two-thirds of this ovary, but three months later the patient returned to him with symptoms of backache and desired another operation. At this time he made a vaginal section and found a small tumor, the size of a filbert, embedded in the posterior vaginal wall at the junction of the cervix. In examining the right ovary he found that it had undergone cystic degeneration, the cyst being the size of a hen's egg. The cyst contained ovarian structure, and was unquestionably the remnants of the right ovary. Resection of a cystic ovary or the puncture of cysts of the ovary, followed by swabbing with carbolic acid and alcohol, and sterile water, gave satisfactory results.

Dr. George J. Engelmann said all were agreed that it was desirable to leave as much of the tissue as would preserve the sexual activity, and the question arose, How much could be removed and the menstrual function still be preserved, thereby relieving the patient? He mentioned a case that he had operated upon some twenty years ago, in which there was a large ovarian tumor on the left side, with the tube adherent. On the right side there was a cyst the size of an orange, with a long pedicle, and apparently the tube was partially adherent and diseased. The entire left tube and ovary were removed. The patient menstruated regularly from the day of the operation, and had done so ever since. A larger part of the right tube was left, the pedicle being about one-half the thickness of a lead pencil. With the small amount of ovarian tissue left and with a part of the tube, the function of menstruation was preserved.

Dr. J. G. Earnest stated that the physician should always make a plain statement to the patient as to what she might expect from a conservative operation, or from a radical operation.

Dr. A. M. Cartledge did not think the association should go on record as advocating the removal of both ovaries in young women simply because they had pus tubes. Many young women consulted the gynecologist with acute suppurative salpingitis, but in whom the ovaries were normal, and he thought it was outrageous to unsex them. In every case, he recommended leaving a piece of an ovary, if it was not larger than a grain of corn.

Dr. Richard Douglas thought the last speaker had misunderstood the essayist, in that he did not advocate the removal of healthy ovaries when the tubes alone were affected, but discountenanced the resection of infected ovaries, and with the essayist he agreed in this particular. When an ovary was infected, any conservative procedure was useless; when the tube was involved, and not the ovary, the ovary should be left, under all circumstances.

Dr. Edwin Walker made a plea for more accurate diagnoses in these cases, saying that many of these patients suffered from other diseases or neuroses independently of the genital organs.

The Surgical Treatment of Pancreatic Cysts, with Report of Two Cases.—Dr. A. Morgan Cartledge of Louisville, Ky., said that cysts of the pancreas, while rarely encountered, were still the most common pathological condition of this deep-seated organ that surgeons were called upon to treat. There was little doubt but that the field of surgery, as applied to the pancreas, should be extended, and some of the more recent contributions to the subject should attract the attention of surgeons to this almost unexplored region of the abdomen. According to Böckel, the cases treated surgically now numbered 115. In ninety-nine of those the cyst was opened at the first sitting, with the result that ninety-two recovered and seven died. In sixteen cases the cyst was opened subsequently, after the formation of adhesions, with sixteen recoveries and no deaths. This spoke well for the treatment by incision and drainage. The same author had collected twenty-five cases in which extirpation, either complete or partial, of the sac was practised, with four deaths. A comparison of the results shown by statistics would seem to indicate that incision and drainage should be practised as a routine procedure in pancreatic cysts, and yet a closer study of the clinical forms which the cyst might present, together with a closer study of the convalescence of the drained subjects, might cause surgeons to attempt extirpation of the sac more frequently and with better results. The author's experience with the treatment of pancreatic cyst was limited to two cases, one treated by incision and drainage, and the other by enucleation of the cyst. Both patients recovered. These cases were reported in detail.

Dr. C. H. **Mayo** mentioned briefly three cases of pancreatic cyst that had come under the observation of his brother and himself. In one case fat necrosis was especially noticeable.

Dr. L. H. **Dunning** had never encountered but one case, and this was associated with stone in the ampulla of Vater. The cyst was large, and there was an extensive accumulation of bile within the gall-bladder, with dilatation of the gall-bladder. Chocolate deposits were noticed in the cyst wall.

Dr. **Richard Douglas** said that Mr. Jordan Lloyd had emphasized the fact that there were true and pseudocysts of the pancreas. The recent work of Robson, Mayo, and others, he thought, had shown the relation between gallstones and pancreatic disease, and it was possible that in this connection we might have a true solution of the pathology.

Dr. **Alexander Hugh Ferguson** mentioned three cases, one of them being a hydatid cyst of the pancreas. This case he treated by drainage, suturing the pseudocyst to the skin, and packing with gauze. The patient, a girl, recovered.

The Curse of Gonorrhœa.—Dr. **Joseph Taber Johnson** of Washington, D.C., followed with a paper on this subject, saying that so many sad cases of pelvic disease of specific origin were constantly coming under the care of those in charge of the female clinics in the dispensaries, and in the gynecological wards of our public hospitals, that it was almost impossible to overestimate the importance of this subject. The evidence was indisputable and overwhelming that many women lost their lives annually from the pelvic inflammation, caused by these complications, and that thousands probably lost their health, or their power of conception, from the same cause. From the best statistics he had been able to obtain, there were 300,000 women in this country leading lives of prostitution, and the estimate was made by health officers and the superintendents of police in thirty large cities, who made reports on this subject, that for every woman who regularly resided in a house of ill-fame, there was at least one, if not more, just as bad, who never or rarely became known to the police. This would give half a million, at the lowest estimate, of candidates for this disease in our country alone. The chief danger of gonorrhœa in the female was the infection of the uterus and uterine appendages. Gonorrhœa was the chief source of salpingitis and pelvic peritonitis. Other complications were mentioned by the essayist. The point which he laid the greatest emphasis on was that gynecologists should make themselves much more certain in the future than they had done in the past that patients of both sexes were absolutely cured, beyond the danger of a relapse, before they were dismissed from further observation, control, and treatment.

Chronic Appendicitis and Movable Right Kidney.—Dr. **Walter P. Manton** of Detroit, Mich., stated that while the practitioner had become familiar with the symptoms and diagnosis of acute appendicitis of the chronic form, which was often productive of great physical distress and suffering, but little was as yet known. As an etiological factor in the production of chronic appendicitis he called renewed attention to movable right kidney, the association of which with appendicular disorder was first pointed out by Edebohls, in 1894. In the writer's experience movable kidney was the most frequent cause of chronic appendiceal disease. In two hundred consecutive cases from his notebooks the essayist found that the right kidney showed an abnormal mobility in 36½ per cent., and in 67⅓ per cent., nearly, of these cases a diagnosis of chronic appendicitis was also made. In 22½ per cent. of this number the diagnosis was confirmed by operation. Among the other cases some were of too mild a type to demand immediate intervention, the patient refused operation, or was now waiting for this to be performed. Regarding the manner in which movable right kidney gave rise to the appendical affection, Dr. Manton accepted the theory of Edebohls as the most satisfactory yet offered, namely, that the kidney compresses the superior mesenteric vessels between the head of the pancreas and the spinal vertebræ, thus interfering with the circulation in the appendix, and giving rise to congestion and subsequent inflammation in that organ. He laid special stress upon two points: (1) That in obscure abdominal conditions a diagnosis should not be attempted until movable kidney and chronic appendicitis could be excluded by careful abdominal palpation; and, (2) that when nephroptosis and appendicitis were present, operations upon the uterus and adnexa would not be followed by cure of the patient unless one or both of these conditions were also removed.

Dr. **Bacon Saunders** said that, having had a number of both conditions to deal with, he had not had experience which would lead him to believe that the two conditions were so commonly associated as the paper would seem to indicate. In other words, his experience had not led him to believe that most of his cases of chronic appendicitis had depended upon movable kidney, although it was possible, and the condition might have been overlooked.

Dr. **Edwin Walker** had noticed the co-existence of the two diseases, but he had not found it in a large number of cases.

Dr. **Robert T. Morris** stated that since Edebohls published his paper he had given considerable attention to the association of the two affections, and quite frequently, when there was a loose kidney pressing upon the superior mesenteric vein, he had found that there was congestion of the cæcum, and if a careful palpation was made, the appendix would be found to be tense, and infective appendicitis would be more commonly found in such cases.

Dr. **Charles P. Noble** stated that he had operated on one hundred cases of movable kidney, and so far as his observation went, he did not think there was more than half a dozen of that number in which the appendix was involved.

Dr. A. M. **Cartledge** thought the two affections were more frequently associated than according to the statistics mentioned by the essayist.

Dr. **Alexander Hugh Ferguson** did not think there was any relationship between appendicitis and floating kidney *per se*. The most extensive cases of floating kidney he had encountered had no appendicitis whatever. The kidney might be down on the brim of the pelvis and resting on the tip of the appendix without disturbing it.

Dr. **Simon P. Kramer** spoke of the occasional occurrence of appendicitis with floating kidney.

Dr. C. H. **Mayo** said there was one class of cases of floating kidney which was very movable. One could fix the kidney and obtain a good result, and in some of these he was now removing the appendix at the time the kidney was fixed, to determine, if possible, the relationship between the two affections.

Dr. W. P. **McAdory** did not think movable kidney had much to do in causing chronic appendicitis, yet the two conditions might occur frequently at the same time.

Dr. **George H. Noble** of Atlanta, Ga., described a new operation for complete laceration of the perineum, which consisted in splitting the rectovaginal septum, dissecting the lower end of the rectum from the vagina and drawing the anterior rectal wall down through and external to the anus, converting a complete tear of the perineum into an incomplete laceration. The steps of the operation were given in detail.

Pregnancy and Labor Following Complete Nephroureterectomy.—Dr. J. Wesley Bovee of Washington, D. C., in a paper with this title, stated that the removal of the kidney had become a frequent operation and no longer excited surprise or comment upon the part of the medical profession. It was well understood that removal of a kidney, the function of which had not been previously suspended, entailed additional eliminative work upon the kidney of the other side. It must be admitted that one kidney was rarely able to perform the functions of two healthy ones, and that any extra taxation upon its eliminative powers incident to autointoxication of various forms, was liable to seriously embarrass its functional activity. When nephrectomy had been done for renal calculi, with pyonephrosis or tuberculosis, the same condition was liable to be present, in some slight degree at least, in the remaining kidney. Its function was accordingly interfered with. Various investigators had found a marked toxicity of the urine during pregnancy. Nephritis during this condition was very common. Winckel claimed 2 per cent. of women that were healthy before pregnancy had albumin in the urine during pregnancy, and, further, that 6 per cent. of all pregnant women had albuminuria. One notable fact in connection with the toxæmias of pregnancy, or uræmia, was that the amount of urea in the urine was always found markedly diminished. Another important matter in conjunction with pregnancy and labor was the changes in arterial tension which varied during and following labor. His own case of complete nephroureterectomy stood alone. The operation was done March 18, 1901, for pyonephrosis, renal calculi, and miliary abscesses in the ureter. April 15, 1902, after a normal labor of six hours, the patient was delivered of a male child weighing ten and one-half pounds. On the third day after delivery she complained of intense pain diffused over the abdomen, which on the following day became localized along the course of the left ureter. There was tenderness for several days after cessation of the pain in this region. The urine was carefully watched for calculi, but none found. Since the birth of her child she had breast-nursed it and had remained in splendid health. A question of vital importance was the permanent effect of pregnancy and labor upon the remaining kidney. In the case of Steinheil, the patient succumbed to the extension of the tuberculous process to the remaining kidney. Whether pregnancy and labor caused this extension in part or entirely could not be determined. Certainly, the woman had not suffered from renal trouble during the seven years following nephrectomy, but died one year and nine months after delivery. In Schramm's case, no history of the patient subsequent to her discharge from the hospital was given. In the writer's own case, the condition of the remaining kidney did not seem to be worse than before pregnancy, and he had no doubt others had met with cases similar to these. There was little doubt that pregnancy and labor following nephrectomy seriously jeopardized the life of the patient; that the renal complications must necessarily be greatly increased, and therefore induction of premature labor and other forms of treatment of these complications more frequently necessitated. In these cases the evidence of permanent impairment of the remaining kidney, as a result of pregnancy and labor, was by no means convincing, but the writer's individual opinion was, as records were made of these cases, that such effects would be apparent.

Personal Experience with McGraw's Method of Gastroenterostomy.—Dr. Samuel Lloyd of New York read a paper on this subject, in which, after quoting from Dr. McGraw's articles, he reported seven cases, all of them for cancer except one. All recovered from the operation. One of the patients was still alive. This was a stricture of the stomach due to adhesions, which drew the pyloric end out into a long tube and caused it to bend on itself. Of the others all, except two, died from exhaustion from progress of the growth after several months and without signs of obstruction. One was lost sight of and the other died from an involvement of the anastomotic opening in the cancerous growth and consequent secondary closure of the new opening. The writer said that his experience showed that the method was an admirable one; that it was efficacious, and that it was rapid in execution. It had advantages over the button, in that the ligature, after it was tied, was extremely small and readily passed through the intestine, avoiding the danger of a heavy mass retained in an already diseased and ulcerated viscus, and that the opening in the stomach could be regulated to suit the case in hand. In one of his cases the rubber ligature broke, and the operation had to be completed by suture. This accident could probably be avoided by boiling the ligature with the rubber glove instead of with the instrument. With this method of operating there was no danger of soiling the peritoneum by the escape of stomach or intestinal contents, and consequently no intestinal clamps were required. The method was also applicable to the entero-enterostomies, which were made to avoid the vicious circle, and probably to cases of incomplete intestinal stenosis. It was not applicable to complete obstruction. Feeding could be commenced at the end of about forty-eight hours, and could be increased from day to day.

He advocated, in operating for pyloric obstruction, that from eight to ten ounces of peptonized milk and one ounce of whiskey be introduced through a needle into the intestine below the point of the anastomosis during the operation. Its possible regurgitation during the operative manipulation could be prevented by pressing it well down along the intestine, or by the application of an intestinal clamp.

The President's Address.—This was delivered by the President, Dr. W. E. B. Davis of Birmingham, Ala. He spoke, first, of the early history of the association, and the events immediately preceding its formation. He recommended, in addition to honorary members, that the association have another class, to be known as life members, these to be composed of men of great eminence who were more than sixty-five years of age, or who had been members twenty years, and had attended 50 per cent. of the meetings. He suggested that Dr. J. McFadden Gaston of Atlanta, Dr. R. B. Maury of Memphis, and Dr. Thaddeus A. Reamy of Cincinnati, be recommended by the council for this class of membership. He advised the association to limit its membership to two hundred. He urged the members to establish a memorial to the association in Birmingham, the birthplace of the organization. He insisted upon what he asked for last year for the American Medical Association in his presidential address before the American Association of Obstetricians and Gynecologists. He said the national special societies had wielded a wonderful influence in the medical profession, and that medical literature had been enhanced in every way by them, and as individual societies they should be encouraged, but their union into a national congress was not conducive to the best interests of the medical profession. With the adoption of the new plan of organization, providing for a house of delegates to take charge of all business matters in the American Medical Association, more time would be provided for scientific work. He said: "The special societies, composed, as they are, of leaders in the several specialties, are under obligation to the American profession to assist in the better organization of these sections. Many of the members of these societies are officers and active working members of the sections of the American Medical Association, and can accomplish this result. There must be one class of membership for the sections that can be held by only those who are recognized as teachers and leaders to make membership very desirable and sought after." He would suggest that this class be known as Fellows, and that they pay in addition to the annual dues of the association $5 annually for section dues, which fund would be expended in the publication of the proceedings of the section. The officers and authors of papers should come from the Fellows. All members would have the privilege of taking part in the discussions, and thus an opportunity would be afforded for the ordinary or association members to show themselves worthy of a fellowship. Such an organization of the sections, with volumes of transactions, publishing a list of the Fellows, would give stability and permanency to the section work that could scarcely be had in any other way. With the House of Delegates for the general association, and the roll of Fellows and association members for each of the sections, it would become the most scientific and influential medical organization the world had ever known. He stated that the South had suffered greatly from the removal to the larger cities of the East and North of many of its ablest surgeons and gynecologists. This was due in a measure to the poor fees received by Southern surgeons. With the South's great increase in wealth this should no longer obtain. The South had now a population of only five millions less than the whole country forty years ago, and its total wealth was now as much as the United States in 1860. In the language of Mr. Edmondson, "In natural resources and advantages for the creation of wealth, no other section of the world can equal the South." Dr. Davis paid a tribute to the medical profession of the South, and spoke of McDowell, Sims, and Battey as epoch-makers in surgery. He also referred in glowing terms to the work of Dudley, Paul F. Eve, Warren Stone, Dugas, and Pope. Of the many in recent years, who had done excellent work, and who were now dead, he mentioned the names of McGuire, Yandell, Briggs, Rogers, Sr., Kinloch, Westmoreland, Sr., Campbell, Gilmore, Nott, Mastin, and Richardson.

Indications for Extirpation of the Gall-Bladder.—Dr. Maurice H. Richardson of Boston read a paper on this subject, in which he drew the following conclusions: (1) Certain lesions in themselves demand removal of the gall-bladder whenever possible. Such are new growths and gangrenes. (2) Certain other lesions of the gall-bladder are better treated by extirpation. These are the contracted and inflamed gall-bladders, with thickened walls. All gall-bladders which do not permit of easy and efficient drainage should be extirpated, for in such gall-bladders the risk of drainage is quite as great as the risks of extirpation; and the one great advantage of retention is impossible—retention of the biliary reservoir to fulfil the functions of that reservoir and to permit, if necessary, renewed drainage for future years. (3) Drainage is preferable in the dilated and infected gall-bladder, which, however, is neither gangrenous nor, to any great extent, changed—the slightly thickened gall-bladder containing gallstones and infected bile. This gall-bladder will, after drainage, become normal and therefore capable of fulfilling the functions of a gall-bladder. Through it the biliary passages will become effectually drained after subsidence of the temporary swelling about the cystic duct. (4) As a rule, drainage rather than extirpation is demanded in acute cholecystitis with severe constitutional symptoms, when the bladder is dilated or, at least, not contracted. (5) In chronic infections of the gall-bladder, with dilatation and thickening, and especially when a stone is impacted in the cystic duct, extirpation is the preferable operation, unless the stone can be dislodged backward into the gall-bladder, in which case drainage is, if not preferable, quite as advantageous as extirpation. (6) In simple gallstones, without visible evidences of infection, or of chronic changes incompatible with complete restoration of function, simple drainage of the gall-bladder is indicated. (7) In chronic pancreatitis, associated with gallstones or not, drainage through the gall-bladder is indicated.

Anterior Transplantation of the Round Ligaments for Displacements of the Uterus.—Dr. Alexander Hugh Ferguson of Chicago read a paper on this subject. He said it was now over six years since he first carried out the principle of this operation. The abdominal wall was opened in the mid-line in his first two cases. He then thought it better to enter the abdomen through each rectus muscle, the skin alone being cut in the median line. After doing fifty cases in this manner, he returned to the one incision in the adbominal wall, and that at the linea alba, then bringing the round ligaments through stab wounds, one in each rectus muscle. In about one-half of these cases he severed the round ligaments and brought their stumps through the rectus muscle, while in the remainder the ligaments were not cut at all. With this technique there was danger of bowel or omentum, or both, slipping between the transplanted round ligaments and the bladder and producing such complications (strangulation of bowel, etc.) as had been known to occur after Kelly's suspension and other methods of hysteropexy. In order to prevent these complications, the writer had employed one of two procedures to render it impossible for bowels to slip around the uterus beneath the round ligament: "(1) A continuous suture is made, running along the parietal peritoneum from the puncture in it and rectus muscle downward to the side of the bladder, and back, posteriorly, to the round ligament near the uterus. In this almost circular sweep of the needle and thread the peritoneum is caught up about every third of an inch. When the suture is tied an anteroposterior partition of folded peritoneum is thrown between the iliac and bladder regions on each side. (2) The round ligaments are fastened to the parietal peritoneum on each side from the internal inguinal rings to the artificial openings in the abdomen, through which they are transfixed. The redundancy of the peritoneum and the loose attachment of the parietal peritoneum in these regions enable this part of the operation to be done with comparative ease, especially when the patient is in the Trendelenburg position." The technique of the operation, as the writer now performed it, was given as follows. "Place the patient in the Trendelenburg position. Make a median incision, about three inches in length, through the abdominal wall, the lower angle of which reaches the suprapubic fold, and dissect the fat and skin from the anterior sheath of the rectus muscle on either side of the abdominal incision, corresponding to its lower third. Pass two fingers of the left hand into the abdominal cavity on one side beneath the rectus muscle, already exposed anteriorly, to locate and protect the bladder; then make a stab wound through the rectus muscle, in the direction of its fibers, into the abdominal cavity, between the two fingers, an inch from the median incision and an inch and a half from the pubic bone. Before withdrawing the knife, pass an artery forceps alongside of it into the peritoneal cavity and with it take hold of the round ligament and a portion of the broad ligament beneath it near the uterus. Now insert the suture, which is to prevent the bowel from slipping between uterus and bladder, or for the same purpose, suture the round ligament to the parietal peritoneum, as already mentioned. Then drag the proximal end of the round ligament through the rectus muscle with the forceps already attached to it, and sew it and the subjacent portion of broad ligament to the anterior sheath of the rectus muscle leaving a stump of about half an inch long between the parietal peritoneum and uterus. Deal with the other side in a similar manner, close the abdomen, and the operation is complete. Dr. Ferguson claimed for the operation described the following advantages: "(1) It is easy to perform, because all the structures involved are seen as well as handled while performing it. (2) The uterus is left free in the abdominal cavity, as no stitches or bands are attached to it. (3) There is no interference with the physiological functions of the organ-menstruation, conception, parturition, labor, or involution. (4) It has a wider range of application than any operation known to me."

Intramural Extraperitoneal Anchorage of the Round Ligaments for Posterior Displacements of the Uterus.—Dr. George H. Noble of Atlanta, Ga., said that since doing his first operation for intramural extraperitoneal anchorage of the round ligaments, his technique had been changed to simplify it, and to fortify the abdominal wound against the danger of hernia. The feature of the operation was the intramural extraperitoneal implantation of the round ligaments. Combined transverse and vertical incisions were employed to open the abdomen. The steps of the operation were described as follows: (1) A transverse incision is made through the skin, fascia, fat, and aponeurosis down to the recti muscles. This incision in the ordinary subject should be about one-half inch above the pubis, and should extend laterally to the outer border of the recti. The recti are separated vertically in the median line, and the peritoneum opened in the same direction. The pelvis is investigated, proper attention given to the local pathological conditions, and the uterus raised. (2) A pair of light compression forceps with teeth in end (Senn's) is passed through the abdominal opening and grasps one of the round ligaments near the fundus uteri. By traction on the forceps the uterus is pulled somewhat to that side of the pelvis which is opposite the ligament, held, the perineum is drawn away from the region of the internal abdominal ring, and the ligament itself made taut, so that it may be the more readily recognized in the extraperitoneal manipulations that follow. (3) Just beyond the outer end of the rectus, at the end of the transverse incision, the point of a pair of artery forceps is thrust through the posterior sheath of the muscle, but does not enter the abdomen. The forceps are opened and withdrawn, so that an aperture large enough to admit the index-finger is left. The finger is introduced through this opening into the free peritoneal fat, and feels the round ligament without difficulty, for it is brought into prominence by tension on the forceps which holds its uterine end. (4) The finger is hooked under the extraperitoneal portion of the ligament from below upward, drawing it up into the wound. The sheath of the muscle is then split open by blunt dissection. The sheath and peritoneum are stripped back in the direction of the uterus, completely dissecting the ligament of its covering. It is then drawn out of the wound and a forceps slipped underneath retains it until the opposite ligament is raised and denuded in the same way. If the uterus has been in a state of marked retroversion, the ligaments will have become so attenuated as to allow their approximation in the median line in front of the recti, which approximation will restore the uterus to its normal position. (5) When it has been determined that the ligaments are long enough to meet in the median line, they are each left looped over the forceps, while the peritoneum of the median incision and recti muscles are closed with continuous kangaroo or catgut sutures. (6) The ligaments are next approximated in the median line in front of the recti and tied together. (7) Beginning in one angle of the transverse incision, the cut edges of the aponeurosis are stitched together with a continuous kangaroo suture. When one or two loops of the suture have been passed, the needle, in crossing the interval between the two edges, is made to pass through the ligament. It is well also to pick up a little of the muscle on each side of the ligament, in order to provide against dead spaces. This process is continued as each successive loop is passed, until the center of the incision is reached, when the free end of the suture is clamped and left long. Starting in the outer angle of the transverse incision, but looping in a contrary direction, so that when the two sutures meet their free ends may be on opposite sides of the wound, a second strand of kangaroo unites the edges of the aponeurosis on that side and picks up the round ligament and adjacent portions of the muscles as before. The kangaroo tendons are tied together and the ligaments are thus embedded and firmly anchored between the aponeurosis and muscles. (8) The structures in front of the aponeurosis are closed in the usual manner. If, now, the ligaments have not become stretched very much, or if the recti are very wide, or both, it will not be possible to bring the loop ends of the ligaments together. In this case they may be drawn up and carried only so far as is necessary to replace the uterus and moored as above, or they may be cut off at their distal ends, and their free extremities thus brought together or made to lap in the median line. The author had suspended the uterus by intramural anchorage of the ligaments sixty-seven times with satisfactory results.

Intraabdominal but Retroperitoneal Shortening and Anterior Fixation of the Round Ligaments for Posterior Uterine Displacements.—Under this title Dr. F. F. Simpson of Pittsburg, Pa., referred to the chief objections to some of the other operative measures in vogue, and said: "In common with most of you, I have for years wished for a procedure which would be as widely and easily applicable as ventrosuspension, and which would possess its good qualities without its objectionable features." He then described a simple means of accomplishing this end. It consisted essentially in changing the course of the round ligaments from transverse to nearly an anteroposterior direction; in shortening the round ligaments, so that the weak part was left as slack, the strong part being used to control the movements of the uterus; finally, and especially in effecting these changes beneath or by puckering the parietal peritoneum, thus leaving no bands of adhesions, and no pockets which might strangulate an intestine.

Gas-Bacillus Infection.—Dr. Robert T. Morris of New York reported three cases of gas-bacillus infection which occurred this spring in his practice. He said there were a number of gas-forming bacilli belonging to the colon group —anaerobes, and he believed that it was necessary to make an elaborate study of these bacteria in order to classify and group them properly. The first patient was forty-six years of age, upon whom he operated for myoma of the uterus. The patient was in good condition, excepting for the hemorrhages which furnished the indication for the operation. He removed the uterus, leaving the stump of the cervix covered by peritoneum. The operation was done on April 30, 1902. The following day the patient complained of headache; her typical vital signs for that day being a pulse of 116, temperature normal, respirations 20. There was a bloody discharge from the vagina. The following day she had a temperature of 99.6° F., pulse 102, and respirations 22; nauseated, and suffering from continuous headache. The bloody discharge from the vagina had increased in amount. On May 2 the patient complained of intense pain in the abdomen; headache continuous; temperature 100°, pulse 120, respirations 24 He examined the abdominal wound and found it had healed by primary intention. The subcutaneous tissues on the right side of the abdomen were distended with gas, which was quite abundant in amount, but unassociated with tenderness. On the 3d of May the gas within the bowels caused great distress; headache was continuous; temperature 99° F. pulse 120, and respirations 24. A bloody discharge continued from the vagina. On the 4th of May the patient became very restless, nauseated, had continuous headache, with a temperature of 100.6°, pulse 144, respirations 16. On the 5th and 6th the symptoms were somewhat similar, except that there was gas beneath the skin of the abdomen. He opened at this point, for the purpose of getting a culture, when a great deal of gas escaped as he was going through the skin with a pair of scissors. The specimen became exposed in such a way as to interfere with its integrity, so he had no bacteriological report of this case. The patient died on the seventh day. In the second and third cases specimens submitted for examination showed pure cultures of what appeared to be the bacillus aerogenes capsulatus. These patients recovered.

Dr. Alexander Hugh Ferguson detailed two cases of gas-bacillus infection that had occurred in his practice. He said the bacillus aerogenes capsulatus had its habitat in the soil, like the bacillus of tetanus, and was not, unlike the latter, microscopically. It was not a pyogenic organism, as had been proven by Welch and Nuttall, who had made most extensive experiments with it, and who called it the gas bacillus. It was nothing but the bacillus emphysematosus of the Germans. It found its way into the body on greens, cabbage, etc., and one important point was to clean out the alimentary canal to get rid of it. Another important point was that it found its way into the wound from the finger-nails, hence the great importance of scrubbing the nails, etc.

Dr. J. Wesley Bovee had encountered three cases of gas-bacillus infection, all of them following removal of the appendages for pus. One of the patients died. Autopsy showed the gas bacillus in various portions through the viscera, and particularly in the liver and skin.

Prolapse of the Uterus.—Dr. Charles R. Robins of Richmond, Va., read a paper on this subject. He said the uterus was normally maintained in position by a combination of elements, and not by any one. These were integrity of the pelvic floor, making the pelvis a closed cavity, the uterus being of the same density as the other pelvic viscera, the position of anteversion, and the tonicity of the abdominal walls. A departure from any one of these might cause prolapse and, where several were concerned, it was most frequent. Successful treatment must meet all of the pathological conditions present. Proper preliminary treatment was of the utmost importance. The operative treatment recommended consisted of amputation of the cervix, operation for cystocele, perineorrhaphy, and an operation for maintaining anteversion. This treatment not only cured prolapse, but restored function. If relapse occurred, Edebohls' panhysterokolpectomy seemed to be the only operation for effecting a cure.

Diseases of the Ribs Following Typhoid Fever.—Dr. J. Shelton Horsley of El Paso, Tex., reported the case of a man, forty years of age, in whom disease of the left sixth and seventh costal cartilages, the anterior end of the sixth rib, and part of the sternum developed a few weeks after convalescence from typhoid. The abscess had been opened, and later the resulting sinus curetted before the patient came under his care. Then, two extensive resections, involving a portion of the sixth rib, the costal cartilage of the sixth and seventh ribs, and part of the sternum had to be performed before a complete cure was effected. He called attention to five peculiarities to differentiate post-typhoid disease of the ribs from similar affections of other bones: (1) The marrow of the ribs was a particularly favorite seat for the typhoid bacilli; (2) The superficial position of the ribs and their continuous movement made a *locus minoris resistentiæ* more liable to occur here; (3) Necrosis of the ribs very rarely occurred, which was not the case with other bones; (4) Post-typhoid disease of the ribs invariably occurred in adults; (5) Thorough operative treatment was more difficult in the case of the ribs than of most other bones. A table containing forty-eight cases gathered from the literature on the subject and personal communications was appended. An analysis of the table showed forty-eight cases in men and seven in women. This was accounted for partly by the men being more frequently subjects of typhoid, and also by the fact that, owing to the mammæ, the blood supply of the ribs was better in women, and consequently there was greater resistance to infection. The youngest case was a man, nineteen years of age; the oldest, sixty-nine years of age. Periostitis and osteomyelitis were the most frequent diseases. As to treatment, conservative measures were employed in selected cases. If these were unsuccessful, incision and curettage were advocated; and if, after a few weeks the wound had not healed, extensive resection, going well into apparently healthy bone, should be practised.

Gigli Saws.—Dr. Horsley also demonstrated a new holder for Gigli saws. It consisted of a steel arch, with a [illegible] at each end. By means of a set screw at one end, and a traction hook at the other, any desired tension could be obtained on the Gigli saw. When stretched taut it could be used as an ordinary saw or to cut convex surfaces, as in resection of the knee-joint. When used as a chain saw, one end was fastened with a set screw, and the other, after being passed under the bone, was hooked on the traction hook. By taking up or letting out slack with the screw any desired angle might be obtained.

Renal Calculi.—Dr. Mack Rogers of Birmingham, Ala., read a paper on this subject, confining himself to diagnosis and treatment, reporting two cases. He said the clinical history pain, tenderness, swelling and the condition of the urine were the chief guides in arriving at the diagnosis of renal calculi.

Endometritis.—Dr. H. J. Boldt of New York read a paper on this subject. He said it was principally to Ruge of Berlin that the profession owed its more exact knowledge of uterine pathology. He spoke of the glandular interstitial and mixed varieties of endometritis. These formed the basis of all variations or special forms of the disease. He had in a number of instances found the uterine cavity filled with polypoid nodules, in which the quantity removed aggregated from fifteen to twenty c.c. On microscopical examination the picture presented showed adenoma. Such conditions had been classed by some writers as a separate form, polypoid or fungous endometritis. While clinically such designation might be correct, he saw no reason for classing such change under another name than adenoma of the endometrium from the point of view of pathology. Acute interstitial endometritis was recognized by the diffuse invasion of small round cells into the stroma. Frequently pus corpuscles were also seen, and the vessels were found to be pressed apart and compressed by the invasion of the inflammatory corpuscles. Sometimes the round-cell infiltration was found more in the deeper stratum of the mucosa in patches, rather than in diffuse form. Later, when the disease passed into the chronic state, the glands became more or less obliterated, with atrophy of the endometrium. In another form of chronic interstitial endometritis, the stroma cells were enlarged and contained a centrally located nucleus, and resembled sarcoma cells to some extent. The mixed forms of endometritis showed that changes were present in both the glands and the interstitial connective tissue. Of the forms of tuberculous endometritis the ulcerative variety was usually met with. The acute miliary and the interstitial varieties were very seldom seen. Primary tuberculous endometritis was a rare disease. While the etiology of all specific forms of endometritis was well understood, those not depending upon microorganisms and ptomains, in many instances, had uncertain causative factors. The local treatment giving the promptest relief from bleeding in instances of chronic endometritis was undoubtedly to be found in the judicious use of the curette. He would caution, however, that although the operation was comparatively simple, it should not be resorted to indiscriminately, as was being done by many general practitioners; neither should it be done by one who was not trained in the technique of gynecological surgery, because frequently serious results followed its improper employment. Before the operation, it was imperative that a careful bimanual examination be made, to determine whether or not a tubal swelling was present. He had known tubal pregnancy and pyosalpinx to be ruptured as the result of the traumatism produced by the operation in a few instances he had desisted from curetting, and had opened the abdomen subsequently through the disclosures revealed by bimanual examination. If resorted to, the same precautions as to cleanliness should be employed as in a major operation. In his experience about 60 per cent. of the women were relieved from a typical bleeding for a variable period of time by curetting. After curetting it was his custom to make an application of pure carbolic acid to the interior of the uterus. In patients who had not obtained the desired relief by curetting, subsequent local treatment became necessary. The general condition of the patient in all instances required careful supervision. Good food, proper exercise, baths, douches, medicated or plain warm water, as the case may be, were all important adjuvants. After the endometritis had become chronic, it should be treated with intrauterine applications of one of the usual remedies. He preferred a 10-per-cent. solution of carbolic acid. Frequent intrauterine irrigations with large quantities of a mild antiseptic solution also gave good results.

The Use of the Electric-Cautery Clamp in the Treatment of Cancer of the Uterus.—Dr. Charles P. Noble of Philadelphia read a paper on this subject. He presented for consideration a new adaptation of an old principle in the treatment of cancer of the uterus. The electric-cautery clamp was a highly perfected and practicable instrument whereby it was entirely feasible to burn the attachments of the uterus and to leave not only a bloodless field, but one in which the lymphatics were sealed by a thorough cooking or roasting process. Hysterectomy performed by means of the electric-cautery clamp possessed all the advantages of any of the methods heretofore in use, and had in addition certain advantages peculiar to it alone. These especial advantages were: (1) More tissue outside of the uterus was removed or cooked than by the classical methods. (2) All the connections of the uterus were severed either through tissue which had been cooked in the bite of the cautery lamp, or these connections had been severed with the electric-cautery knife. In this way the lymphatic vessels were sealed either by the burning or the roasting process. Whatever the risk of implantation of cancer upon the field of operation might be, by this means it was greatly lessened or done away with. An exception to the above statement must be noted, in that the attachments of the bladder to the uterus were severed in the usual way. (3) Much less blood was lost than was usual with the classical technique, and a dry, bloodless field was left after operation. In referring to the history of the development of the electric-cautery clamp, Dr. Noble referred to the admirable work of Keith and Byrne.

It remained for Dr. A. J. Downes of Philadelphia to adopt the theories of his predecessors and to develop a thoroughly practicable electric-cautery clamp. Dr. Downes used the method wherever there were pedicles to deal with, having abandoned the ligature in favor of the cautery clamp. The technique of hysterectomy by the electric-cautery-clamp method was described in detail. The essayist had operated five times by this method. Dr. Downes had used the method in cancer of the uterus in two vaginal hysterectomies, two vaginoabdominal hysterectomies, and one abdominal hysterectomy upon his own patients; also in one vaginoabdominal hysterectomy operated on for Dr. Hirst, and two abdominal hysterectomies operated on for Dr. Kelly. In closing, the essayist said that some years must elapse before the actual value of the electric-cautery clamp in the treatment of cancer of the uterus could be determined, but in view of the results secured by Byrne and of the positive theoretical advantages it had over the ligature method, it was reasonable to expect that it would give a larger percentage of cures than the older methods, more especially in cancer of the cervix.

The following papers, whose authors were present, were read by title, owing to lack of time: "A Case of Ovarian Fibroma," by Dr. H. A. Royster of Raleigh, N. C.; "Fracture of the Spine, with Report of Three Cases," by Dr. Howard J. Williams of Macon, Ga.; "Spinal Analgesia," by D. E. D. Martin of New Orleans, La.; "The Treatment of Posterior Uterine Displacements," by Dr. Edward McGuire of Richmond, Va., and "Dependent Drainage in Acute and Extensive Intrapelvic and Intraperitoneal Infection in Men by Incising the Perineum Separating the Rectum from the Prostate and Bladder, and Puncture of the Rectovesical Pouch of the Peritoneum," by Dr. Hugh M. Taylor of Richmond, Va.

The council presented the following preamble and resolution, which were adopted:

"Whereas, Dr. W. E. B. Davis, during twelve years of faithful service as secretary of the association, declined to draw any salary for his services, expecting in time to establish some suitable memorial of this association with the fund created; therefore be it

"*Resolved*, That in consideration of this fact, two thousand dollars, a sum far less than the salary offered would have amounted to, be appropriated for the establishing of a memorial in Birmingham, Ala., the birthplace of the association; and that this memorial be placed in the Charity Hospital of that city as a ward to bear the name of the association."

The following officers were nominated and elected for the ensuing year: *President*, Dr. J. Wesley Bovee of Washington, D. C.; *First Vice-President*, Dr. Bacon Saunders of Fort Worth, Tex.; *Second Vice-President*, Dr. Christopher Tompkins of Richmond, Va.; *Secretary*, Dr. W. D. Haggard, Jr., of Nashville, Tenn.; *Treasurer*, Dr. Floyd W. McRae of Atlanta, Ga. Place of meeting, Birmingham, Ala.; time, the week preceding Christmas, 1903. Chairman of Committee of Arrangements, Dr. John D. S. Davis of Birmingham, Ala.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held November 10, 1902.

John B. Walker, M.D., Chairman.

Supernumerary Breast in the Axilla of an Adult Male.—Dr. Frederick Griffith presented photographs of a case of supernumerary breast in the axilla of an adult male. He was indebted to Dr. James F. Connelly of the Army Medical Corps, on duty in Africa, for the report of the case. The subject was a bushman, twenty-five years of age, who had six wives and a number of children. The breast referred to was a true supernumerary mammary gland having no connection with the regular breast. It was bounded in front by the outer border of the pectoralis major muscle, was freely movable, and had the typical doughy feel of the female breast. There was a well-developed nipple upon it. No fluid could be obtained from the breast. The speaker said that no similar case was reported in the literature.

Inguino-Superficial Hernia.—Dr. A. V. Moschcowitz presented this paper (to be published later).

Dr. A. A. Berg said that there had been admitted to the Mount Sinai Hospital this summer a boy of six years in whom both testicles and both cords descended through one ring into the scrotum, the other ring and the other side of the scrotum being absolutely empty.

Dr. John B. Walker said he had seen quite a large number of cases of properitoneal herniæ, and was of the opinion that the non-descent of the testis was the cause of the development of the properitoneal hernia. Apparently the fibers of the gubernaculum which run to the scrotum were not developed, and the canal was constricted below. When increase of abdominal pressure occurred the hernia came through the ring, and, being prevented from descending, followed the direction of least resistance, *i. e.* upward and superficially. Quite a number of such cases were seen among children. If the ordinary hernia truss were worn it was difficult to so adjust it as to hold back the hernia, and yet allow the testis to descend. If such cases were not operated upon in childhood, the testis would descend, but the hernia would generally become adherent to the cord, and hence with the descent of the testis came the hernia adherent to it. It was feasible, by careful dissection, to save the testicle and cure the hernia by a typical Bassini operation.

A Case of Gonorrhœal Peritonitis.—Dr. Charles R. L. Putnam presented a girl of six years. After being sick for several days she suddenly developed severe pain in the right lower quadrant of the abdomen. There was a vaginal discharge, proved to be gonorrhœal in nature by Gram's method of staining. A diagnosis of gonorrhœal peritonitis was made, and an immediate operation was decided upon. The appendix was considered the probable cause of the trouble, although the possibility of gonorrhœal peritonitis was considered. The appendix was removed, and although it contained about twenty pinworms, careful examination of its interior showed no ulceration. Pus was oozing from the right tube and ovary, and pus was scattered over the intestine. The ovary and tube were removed. The cavity was flushed out and drainage established. At the completion of the operation the patient was in collapse, but rallied promptly, and made an uneventful recovery. In a recent report in the *Johns Hopkins Bulletin* thirty-nine such cases were reported, and in one or two of these the patient was even younger than the girl just presented.

Typhoid Perforation in a Child of Six Years; Successful Operation.—Dr. C. A. Elsberg presented a girl of six years, who had been admitted to the children's service of Dr. Koplik at the Mount Sinai Hospital on July 26, 1902, with typhoid fever. The case ran a typical course. On August 13 the temperature suddenly rose above the usual range, and the child went into collapse. There was found to be a leucocytosis of 18,000. Seven or eight hours later she began to vomit, the abdomen became hard and the pulse rose to 190. A diagnosis was made of perforation, and shortly afterward Dr. Elsberg saw the case and operated. The pulse varied between 180 and 200 and the temperature was 105° F. A small perforation was found about eight inches from the ileocæcal junction, through which fecal matter was oozing. The perforation was closed, the abdominal cavity sponged out, and the cavity closed with drainage. The operation occupied eleven minutes. About eight days after the operation an acute vaginal discharge appeared, and bacteriological examination showed an almost pure culture of typhoid bacilli. This cleared up in a few days under ordinary douches, and after that recovery was uneventful. The speaker said he believed this was the youngest child on record having typhoid perforation.

Inguinal Interstitial Hernia in a Woman; Ovarian Cyst in Hernia.—Dr. Elsberg presented a woman of thirty-eight years who had been admitted to the service of Dr. Howard Lilienthal. For eight years she had had a large hernia on the left side. On admission there was a tumor larger than a child's head in the left inguinal region. The upper part of the tumor appeared to be cystic, while the lower portion evidently contained intestine. A tentative diagnosis of ovarian cyst in the hernia was made, although the result of vaginal examination was negative on this point. It was noticed that the hernia ran between the layers of the abdominal wall, and it was in this interstitial portion that the cystic mass was felt. She was operated upon on June 28. It was found that the upper or cystic portion extended from the level of Poupart's ligament about four inches and contained an ovarian cyst. The parts were very much relaxed, and a typical Bassini operation could not be done. The neck of the sac was only one inch in diameter.

Dr. A. Ernest Gallant, speaking of Dr. Putnam's case, said that it was chiefly of interest in connection with diagnosis. Last spring a woman had been brought to him with all of the symptoms of appendicitis. In addition, there was a vaginal discharge, a rapid pulse, and a temperature of 103° F. On operating, pus was found to be pouring out of both Fallopian tubes, and the tubes were removed. There was a mass of exudate on the right side, but no appendicitis.

Dr. John F. Erdmann said he had recently seen a woman of forty-six in partial collapse from what was supposed to be a perforation of the bowel in the sixth week of typhoid fever. On operating he had found a perforation of the gall-bladder without any evidence whatever of recent cholecystitis. There were two very small stones in the bladder, but they had apparently had no influence in causing ulceration.

Dr. A. A. Berg referred to a case of typhoid perforation occurring last summer in a woman in about the third week of typhoid fever. There had been no high leucocyte count at any time. The abdomen was opened and the intestine found to be only injected. The free peritoneal cavity contained gas and a considerable quantity of purulent fluid. The perforation was small, and the edges of the opening were gangrenous. The peritoneum was cleaned and the peritoneal cavity closed without drainage. The skin wound was also closed, the idea being that this would allow of the continuance of tub baths. The patient did well for three days, but on the fourth day she unexpectedly went into collapse and died six or eight hours afterward. The post-mortem examination showed the peritoneal cavity clean, but the abdominal wound was the seat of very extensive gaseous infection, and this had raised the question as to the wisdom of closing the abdominal wound in the manner described. In the future he would be disposed not to close the abdominal wound in this way.

Dr. Joseph Wiener, Jr., said that the more he saw of typhoid perforation the less he felt he knew about this subject. Reference was made to a case in which consent to operate could not be gained for about thirty-six hours. At the operation there was diffuse peritonitis and thick layers of fibrin, one of which had to be stripped off before a large perforation could be found.

There were several large ulcers in the ileum almost on the point of rupture. The man did well for several days, and then died with symptoms which suggested that death had been caused by a rupture of another ulcer. He was disposed to think that this patient would have done just as well, if not better, by refraining from operating. In another recent case, occurring in a child of twelve, in Dr. Koplik's service, the classical signs and symptoms of typhoid perforation were present, including a sudden rise in the leucocyte count from 7,000 to 11,600. Operation was urged, but was refused. The child now had a perfectly normal temperature, and was apparently well. All of those who had seen this child had insisted upon the correctness of the diagnosis of typhoid perforation.

Dr. Moschcowitz said he had operated upon two cases of typhoid perforation last summer, one of them occurring about the twelfth day. The patient had been walking around up to the day before admission to the hospital. In the other case perforation occurred on the sixty-eighth day. Both cases terminated fatally.

Dr. Elsberg said that there was little doubt that the leucocytosis increased at the time of the perforation, but it often diminished again within a very few hours, and hence if the leucocyte count were not made at this particular time the surgeon would probably be misled. For this reason the leucocyte count was not reliable, although useful as confirmatory evidence. He saw no reason why typhoid perforation should be treated differently from other kindred abdominal accidents. The iodine reaction he had found absolutely useless because it was present when there was the slightest suppuration present, even a small boil.

Stomach Tube Removed from Stomach.—Dr. A. A. Berg presented a stomach tube that had been removed by operation from the stomach of an infant. A child of two years and a half had been taken to a physician's office suffering from gastritis, and had been subjected to stomach washing. While this was being done a sudden movement of the child's head separated the tube from the glass connection with the funnel, and the tube slipped down into the child's stomach. The tube, which was nineteen inches long, was easily located by palpitation in the stomach. It was lying near the cardiac end doubled upon itself. The stomach was opened and the tube removed, and the child made a rapid recovery.

Bullet Wound of the Frontal Lobe.—Dr. Berg also presented a bullet and a piece of bone removed from the frontal lobe of the brain. The patient had attempted to commit suicide on the steps of the Mount Sinai Hospital. There was a wound of entrance about two and a half inches above the eye, and as the house surgeon found a wound of exit in the temporal region he inferred that the bullet track was superficial, and accordingly merely kept the patient under observation. The next day, when Dr. Berg saw the man, he found a depressed fracture of the frontal bone, and on operating, found the dura mater torn. The patient made a good recovery.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held November 13, 1902.

Rowland G. Freeman, M.D., Chairman.

Report of a Case of Meningitis Treated by Lumbar Puncture.—Dr. S. Ormond Goldan reported this case. The puncture was not done primarily for the purpose of establishing the diagnosis, but as a means of cure. The patient was a child of eleven months, whom he had been called to see because of a persistent vomiting followed by an apathetic condition and convulsions. A purgative and warm bath had no effect, and the vomiting and convulsions continued. Later there was a complete paralysis of the right side of the body with left ptosis, and the child became practically comatose. The temperature rose steadily, reaching 105° F. After the fifth day the convulsions ceased. A swelling appeared at the fontanelle on the second day, and increased up to the fifth, at which time the lumbar puncture was made between the third and fourth lumbar vertebræ and 14 c.c. of fluid were removed. The child's condition began to improve at once, and at the end of two weeks the little one was apparently well. The puncture caused a reduction of the fluid tension, and so favored absorption, just as removal of a little fluid in a case of pleurisy with effusion often leads to the complete absorption of the remainder of the fluid. The speaker said the procedure was simple, almost free from risk, and not only aided in establishing the diagnosis but was a therapeutic measure of distinct value.

Report of a Case of Achondroplasia.—Dr. Charles Herrman presented this case. The patient was a boy who had been born after an easy and normal labor, and had been wet-nursed most of the time for the first ten months. At the end of this time the child was in very poor condition. He did not begin to sit up until the age of five years; he began to stand at six years and to walk at seven years. The first tooth appeared at the age of nine months. The boy was now fifteen years old, but his weight was that of a boy of nine. His height corresponded to that of a boy of seven years, while the head was almost as large as it should be for one of his age. The trunk corresponded to the age of thirteen years, yet the lower extremities were those of a boy of four years and a half. Several radiographs of the boy were exhibited. One of them showed that the head of the humerus was not well fitted into the glenoid cavity, because the latter was poorly developed. The short bones of the forearm were well shown, as also the unusual prominence of the bony points of attachment of the muscles. Inspection of the hands showed that the fingers were nearly all of the same length, and the ends of the phalanges diverged. The femur, instead of being slightly longer than the tibia, was slightly shorter. The marked curvature in the leg was partly due to a curve of the tibia, and partly to a faulty articulation at the knee. The speaker said that the chief pathological process was situated between the bone and the epiphysis. The cartilage cells, instead of being arranged in columns, were placed irregularly in groups. The term fetal rickets had been applied to several different conditions resembling one another, *i. e.* fetal myxœdema and fetal chondrodystrophy or achondroplasia. The great difference between the normal trunk and the length of the extremities was an important diagnostic sign, and, of course, made the diagnosis much easier in a child of this age than in infancy. Many of these children die in early infancy, but if they survive this period they are apt to be very strong and healthy. In many cases the intelligence was nearly normal, but in the boy just presented it was below the normal. As a rule, these cases had shown no improvement under thyroid treatment. This boy had not been under thyroid treatment long enough to allow of saying whether or not the treatment would prove of value, but he doubted if it would prove efficacious.

Adherent Pericardium.—Dr. George M. Swift read this paper. He said that the condition was not very uncommon, there having been eighteen cases seen in St. Mary's Hospital for Children since 1886. The children in that hospital ranged in age from two to fourteen years, and about 350 medical cases are admitted each year. Two specimens illustrating this condition were presented. All of the hospital cases had died, and in most of them a post-mortem examination had been made. On incising the adherent pericardium it was found that the pericardium and the muscle were glued together. During life the administration of cardiac stimulants was apt in these cases to have a bad effect. In many of them no valvular lesions were present, but the presence of murmurs was explained by the way in which the heart was held open by firm union to the chest wall. Enlargement of the liver was often the first sign of adherent pericardium. The larger number of cases originated in rheumatism, though some were the result of the pneumococcus acting upon the pericardium in the course of a pleuropneumonia. Tuberculosis of the pericardium apparently occurred in older subjects. In cases of adherent pericardium there was usually a turbulent action of the heart. On inspection of the chest anteriorly the cardiac impulse would sometimes be found diffused, owing to the adhesion of the pericardium; in other cases there was a drawing in of the intercostal spaces during systole. The liver became enlarged by congestion, sometimes to such an extent as to reach below the umbilicus, and the diminution in the size of this organ was frequently one of the first signs of improvement in the condion of the heart. In the hospital death occurred on an average in about five years after making the diagnosis of adherent pericardium. The prognosis should be fairly good if the patient could have an abundance of nitrogenous food, in order to supply the unusual demands of the system, especially in growing children. The prognosis should be good also if the progress of the rheumatism could be checked.

Dr. Rowland G. Freeman said that the diagnosis of adherent pericardium in children was very rarely made. When pathologist at St. Mary's Hospital for Children he had been impressed with the fact that when Dr. Swift made a diagnosis of adherent pericardium this condition would be found at autopsy; hence, his statements should be given great weight.

Dr. Jacob Sobel said that the so-called paradoxical pulse was considered by the Germans as pathognomonic of this condition, and he would like to know if Dr. Swift's experience supported this view.

Dr. E. Libman said he thought it had been conclusively shown that the paradoxical pulse was not pathognomonic of adherent pericardium. It indicated some interference in the mediastinum, possibly from tumors, as well as from adherent pericardium. It had also been found in cases of open ductus arteriosus.

Dr. Swift said he had endeavored in his paper to refer only to those signs and symptoms which had aided him in making the diagnosis. The paradoxical pulse had not been one of the signs which had proved helpful to him. The first case of adherent pericardium he had seen was in 1886, and occurred in the person of a child of seven years. She had ascites and was tapped. The jaundice, cachexia, and the very great enlargement of the liver led him to suspect malignant disease in the abdomen, yet on autopsy he found simply an enlarged and congested liver with adherent pericardium as the main condition. The number of cases he had seen since then made him feel that the condition was more common than one would infer from the literature. This meant also that acute pericarditis could not be very rare in children. In the girl who had died recently in the hospital, and whom he had expected to present this evening, improvement in the circulatory conditions was associated with diminution in the size of the liver, while increased embarrassment of the circulation was accompanied by a corresponding increase of the liver, so that sometimes this organ reached to the level of the umbilicus. The essential points in the treatment were to carry out a persistent treatment against the rheumatism and to give such children an abundance of nitrogenous food.

Peliosis Rheumatica in Children, with a Brief Review of the Literature.—Dr. Henry Heiman was the author of this paper. He said that the following classification was convenient: (1) Purpura simplex, characterized by hemorrhages into the skin but not into the viscera, and occurring *sui generis;* (2) Purpura hemorrhagica, marked by severe hemorrhages, including hemorrhages from the mucous membranes; (3) Purpura fulminana, and (4) Peliosis rheumatica. Purpura or peliosis rheumatica was characterized by purpuric eruptions in connection with multiple arthritis. Its onset was usually marked with sore throat, mild febrile disturbance and arthritis, particularly of the ankles and knees. The urinary changes were those of acute congestion of the kidneys. Tender nodular infiltrations were sometimes seen beneath the skin. Though relapses often occurred, especially in children, the disease ran a self-limited course, and the prognosis was good. The rash was more extensive than in adults, and more joints were apt to be involved. Recurrences were more common and tender nodes were more often seen. In 1801 the disease had been first described under the name of purpura urticans. Fuchs gave the duration as ten days to two weeks, and said the prognosis was favorable. He laid special stress upon the occurrence of desquamation.

Dr. Heiman then reported the following case, seen in the service of Dr. Koplik. It was interesting because of the multiplicity of the arthritis and the presence of purpuric spots in the mouth and on other parts of the body other than the inflamed joints. The patient was a boy of eight years. On admission there was an eruption on the left buccal mucous membrane, on the hard and soft palate and on both pillars of the fauces. There was a diffuse rash on the neck, in the groins, and on the scrotum and feet. The abdomen was acutely sensitive to pressure. Nodular infiltrations were present on the arm and forearm. The heart, lungs, and spleen were normal. The hæmoglobin percentage was 65, but there was no leucocytosis. The urine was normal, except for a trace of albumin. The bowels moved freely and the stools contained mucus and blood. During the first week in the hospital the symptoms gradually abated and the mucus and blood disappeared from the stools. In the second week spots appeared above the elbows and a systolic murmur developed. It was audible over the lower part of the precordium, was loudest at the apex, and was not transmitted to the left. This murmur disappeared in the third week and most of the symptoms did the same. There were several oscillations of the symptoms and signs, but the boy eventually recovered completely in the course of about three months.

Dr. Jacob Sobel said that most cases of this kind that he had seen had occurred at the time of the year when rheumatism was most prevalent and in many instances there had also been present erythema nodosum. Such cases had responded very promptly to the salicylates. The form known as Henoch's purpura was usually characterized by severe abdominal pain and bloody discharges in addition to the purpura.

Dr. Sara Welt-Kakels said that a few weeks ago she had seen a case of peliosis rheumatica. The patient, a child of four years, had been first brought to the Mount Sinai Hospital Dispensary last July, complaining of pains about the joints of the lower extremities. This was associated with some hemorrhagic spots. The examinations of the heart, blood, and urine were all negative. The child was kept under observation for four weeks, and during this time the rectal temperature varied between 100° to 103° F. A few days later a murmur was heard for the first time at the apex, and this murmur was still present. The spots and the articular pain disappeared shortly after this, but all of the signs and symptoms recurred subsequently. There was at present mitral insufficiency. She would call attention to the fact that Henoch said that he had seen peliosis rheumatica associated with endocarditis.

Dr. C. Herrman said that about two years ago he had presented to the Harlem Medical Association a typical case of Henoch's purpura. The peculiar epigastric pain seen in such cases resembled very closely the crises of tabes, and it was certainly very remarkable that the patient usually recovered from them so quickly. There were some points of resemblance to angioneurotic œdema. It was not impossible that the hemorrhages and the pains were due to vasomotor neurosis of central origin.

Dr. George M. Swift reported the case of a girl of eleven years who had been admitted to hospital from another institution where she had been upon quite a varied diet, including oranges. The first symptoms were those of a cold, followed on the third day by pain in the leg and foot. On admission there were purpuric spots on the trunk and face, associated with much swelling. On the hard palate there was an ecchymotic swollen spot and the uvula and right tonsil were the seat of a submucous hemorrhage. The child's appearance indicated good general health. The temperature was 101.25° F. The urine was normal. Two days later the swelling was less, but the ecchymotic spots had increased considerably. The next day the conjunctiva was ecchymotic and the ears were discolored and swollen, as were also the wrists and hands. The gums were swollen and the stools were tarry. After about eight days the patches on the skin were red and elevated, and had begun to itch. After a week or more the salicylates were stopped, because of the persistence of delirium, and the chloride of calcium was substituted in doses of three grains every three hours. Nearly three weeks later she was able to be up and around.

Dr. La Fetra referred to the swelling of the lower eyelids, a symptom which he said was not common, and sometimes suggested nephritis. He had such a case under observation at the present time. There were tender spots all over the trunk. The only things pointing to rheumatism were sore throat and a temperature of 100° to 101° F.

Dr. Libman said that he had made bacteriological cultures in four or five of these cases with negative results. They gave him the impression of a toxæmia rather than an infection. Sometimes these patients would recover entirely while in bed, and on getting up would have a recurrence of the eruption in the lower extremities, and yet one could hardly explain this on the theory that it was the result of an infection.

Dr. B. Lapowski said that some of the French authors insisted that it was not an infectious, but a toxic disease. The case reported by Dr. Swift showed very clearly that peliosis is not a single disease, but can be combined with a number of others—as, for example, erythema nodosum. In cases occurring in children one should be careful to exclude gonorrhœa—indeed, one should not present a case as an example of peliosis rheumatica without excluding gonorrhœa, whether the patient was a child or an adult.

Dr. Heiman closed the discussion. He said that in the cases giving a papular eruption he had sometimes observed desquamation. The epigastric pain was perhaps best explained as due to a myositis. He thought Dr. Swift's case was an example of a rather unusual form of peliosis rheumatica. The antirheumatic treatment proved as useful as any other, and this pointed rather strongly to the rheumatic nature of this affection.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held November 20, 1902.

Robert F. Weir, M.D., President.

The Harder Variety of Hodgkin's Disease, and a Report of a Rare and Perhaps Undescribed Affection of the Lymph Glands.—Dr William S. Halsted of Baltimore read a paper with this title. It was based largely on eleven cases observed and treated in his service at the Johns Hopkins Hospital, most of them within the past three years. Thanks to the labors of the pupils of Dr. Welch, and especially Dr. Dorothy Reed, they were now in possession of the means of making a positive diagnosis by microscopical examination, and this uniformity of results from the laboratory would, no doubt, lead, in the near future, to better clinical diagnosis in such cases. The distinction by Virchow of the soft and hard varieties was a useful one clinically. The speaker said his experience made him feel sure that many cases of Hodgkin's disease were overlooked. The soft forms were only a step removed from sarcoma, and the hard forms closely resembled fibrosarcoma. Diwtrich, in 1896, had pointed out that the enlargement usually began in one gland and gradually extended to the surrounding groups of glands; rarely, at the outset, did it become generalized, and the glands enlarged without breaking the capsule. The diagnosis of malignant lymphoma could only be made by microscopical examination of an excised portion. From the reported cases, as well as a study of one of his own, he had come to believe that death follows very quickly upon secondary infection of Hodgkin's disease with tuberculosis. That the clinical diagnosis was not always simple was indicated by the number of names under which the disease was known.

Symptomatology.—The chief symptoms were enlargement of the lymph glands, and usually of the spleen, together with progressive anæmia. In one of his cases, both pectoral muscles were the seat of deposit. The tonsils and the follicles at the base of the tongue were not infrequently involved In about one-third of the cases the liver was involved, and sometimes enlarged by the formation of lymphatic nodules. The mammary glands, the lachrymal glands, the glands of the conjunctiva, and the meibomian follicles might also be the seat of the disease. The disease usually began in the cervical glands, sometimes in the lower part of the posterior cervical triangle. The lungs were almost never affected by malignant lymphoma. The examination of the blood showed nothing more than an anæmia. Fever had been described in Hodgkin's disease by most of those who had written on the subject. In every one of his own cases it had been present. Sometimes fever periods of two weeks alternated with like apyrexial periods. The enlarged glands were not always so freely movable as one would suppose from the descriptions usually given. As a rule, these cases resembled tuberculosis very closely. If the cervical glands on one side only were enlarged, it would usually be impossible to make a diagnosis from inspection alone. Apparently, there were cases of lymphatic tuberculosis which presented a picture identical with that of Hodgkin's disease, or at least so much like it that the two could not be differentiated even at the autopsy table. The glands should, of course, be removed unbroken, and in one piece if possible. The glands were often as large as a Madeira nut, but were rarely as large as a lemon; they often varied considerably in the same individual. The septa were, in places, very thick. The bloodlessness of the glands was very characteristic. There was usually also a suggestion of translucency. Hemorrhages might occur, though uncommon in the hard variety. One of the eleven cases at the Johns Hopkins Hospital was treated on the medical side; the other ten on the surgical division. Eight of these had been admitted since 1899; four this year. Ten of the patients were whites and one a negro. Eight were males and three females. Only one of the eleven cases developed tuberculosis. Of the eight operative cases, one could not be traced; all of the others were now living and apparently in good health. Tuberculin was given in all but one case. Dr. Halsted said he had been impressed with the soundness of the work done in the laboratory by Dr. Dorothy Reed, for the accuracy of her diagnoses had never been impeached, though put to many severe tests.

Treatment.—A search through the literature showed that 104 cases of Hodgkin's disease had been reported as cured, yet there was no evidence that a cure had been effected in a single one of them. That some of them had lived four years under treatment with arsenic proved nothing, for some of their cases had lived seven years with practically no treatment. Operation, together with the use of the *x*-ray and arsenic, might possibly effect a cure. The large number of cures following operations upon tuberculous glands gave no hope in Hodgkin's disease.

A Possibly New Affection of the Lymph Glands.—Dr. Halsted then reported a very remarkable case, which they had had under observation for a number of months, but had been unable to throw much light upon its nature. The patient was a German, thirty-three years of age, admitted on February 3, 1902, and discharged in August. The family history was negative. He had had no severe illness until about eight years previously, when the present trouble began with a swelling high up in the right axilla. Even at the outset it was very painful and tender, and was believed to be connected with the lymph glands. The growth was removed at the clinic of Mikulicz, and the pain, although temporarily relieved, returned in eight weeks and had persisted ever since. In the last few months before admission the pain had become much worse. For two years or more there had been swelling above the right collar bone. When this swelling softened the pain and tenderness diminished. The man was somewhat emaciated, and his face wore an anxious expression. The head was held somewhat rigidly. In the supra- and intraclavicular fossa, and over the clavicle, the skin was reddened and thin, and there was a second soft spot a little more external to the other swelling over the clavicle. The pectoral muscle appeared to be infiltrated with the products of inflammation. In the axilla was a mass which appeared to be similar to that above the collar bone. From the time of admission to that of the first operation, six weeks later, there was an intermittent fever, the evening temperature averaging 101° F. Tuberculin was injected three times without affecting the temperature. Professor Mikulicz sent an abstract of this history, and stated that the nature of the trouble had not been clear to him. The first operation, done in Baltimore, was on March 13, 1902. The clavicle, the supra- and infraclavicular regions were exposed, and the clavicle found to be almost entirely destroyed in its external half, and a pathological fracture was present in the other portion. The axilla was nearly filled with material resembling a myxoma. There was no trace of lymphatic glands here. The axillary vein was thrombosed, and there was much connective tissue about the veins of the brachial plexus. Portions of tissue were removed and immediately inoculated into the femoral vein of a dog and into a cavity made in one femur. The pain of which the patient had complained persisted, but was not so intense as before operation. On May 9 a supplementary operation was done, and, to their surprise, it was found that the clavicle had become much larger than its fellow, and the medullar cavity was small. Apparently the disease had not advanced since the first operation On September 15, 1902, the patient returned to the hospital for inspection, and it was found that there was no pain in the wound or evidence of extension of the disease. Dr. Halsted said that he felt sure that this case was an example of a peculiar inflammatory affection of the lymphatic glands. It was hardly conceivable that a new growth, associated with such a large amount of inflammation, should have made so little progress in the course of so many years Although the microscopical appearance of the tissue closely resembled that of tissue from a case of Hodgkin's disease, the naked-eye appearances were totally different. The result of the inoculations was negative and actinomycosis and lues were easily excluded. There were some reasons for believing that the lymph glands were either primarily or secondarily the seat of disease.

Dr. **Joseph Sailer** said that, in the original paper by Hodgkin, at least two, and perhaps three, conditions were confused, and this might afford us some consolation when reflecting upon the present difficulties of diagnosis. About four years ago, in conjunction with Dr. J. Chalmers Dacosta, he had undertaken a study of the pathology of the lymph glands, and this study had impressed him with the great obstacles that must be surmounted. It was difficult to say whether the lymphoid cells or the connective tissue were increased or not. As for the presence or absence of some of the peculiar forms of cells, such as the mast cells, the eosinophiles and the myelocites, very little was known with regard to these cells or their significance. The study of the glands was most important, and he did not mean to decry it, but at present our technique made such a study beset with difficulties. He had often thought that a careful consideration of the physiology of the lymph glands might aid us. It was not unreasonable to suppose that they were capable of secreting certain substances, particularly agglutinins and lysins. Speaking of the relation of pseudoleukæmia to tuberculosis, Dr. Sailer said that he had observed four cases closely resembling pseudoleukæmia. In all four, at autopsy, they had found tuberculous lesions in addition to the changes in the lymph glands. The most careful work in this field had been by Sternberg. There were two reasons for being very cautious about supposing that the tubercle bacilli found in the glands bear a relation to pseudoleukæmia, viz., (1) Tubercle bacilli had been found in other forms of tumor, such as carcinoma and sarcoma, and (2) the lymph glands are particularly susceptible to infection by the tubercle bacillus. Of all the infectious causes demonstrated to exist in leukæmia, he thought only one was worthy of passing attention. The tubercle bacillus had been found a number of times, and Pinkus had stated that the increasing frequency with which it was found led him to believe that it was not impossible that, in the future, all cases would be recognized as of tuberculous origin. Of the four cases of pseudoleukæmia that he had reported, cultures were made in one case, and in this one Dr. Ravenel found a bacillus resembling the tubercle bacillus. In one of the cases tuberculin was injected in adequate dose, but without producing any reaction, though the tuberculin used was of proved efficacy. If it were believed that all forms of pseudoleukæmia were due to a common etiological factor, it should be said that there was not enough evidence to warrant the statement that this was the cause, though the evidence pointed very strongly that way. However, he was of the opinion that there were various conditions characterized by enlargement of the lymph glands, due to various etiological factors, and that some of these conditions would be successfully shown in the future to be due to infections with the tubercle bacillus.

Dr. **H. M. Biggs** said that, during the last two years, he had had five cases of Hodgkin's disease under observation, but in none was it possible to obtain an autopsy. One case was strongly suggestive of tuberculosis. Very large doses of Fowler's solution were given. The fever continued for about three weeks, but gradually fell to the normal, and the swellings markedly decreased. After an interval of two or three weeks there was a second period of fever, very much like the first one. The large doses of arsenic were continued, and the fever went away, as in the first instance. The man improved rapidly, and was discharged from the hospital after three months, at which time he was suffering from well-defined pulmonary tuberculosis. This was the only case he had seen in which the decrease in the size of the glands, which was not an uncommon occurrence with the use of Fowler's solution, was not followed by a speedy recurrence. Another case exhibited changes in the blood shortly before death, which strongly suggested lymphatic leukæmia. The speaker said that he fully believed that Hodgkin's disease was an infection, most probably tuberculous, and that several types had been included under this one name

Dr. **Arpad G. Gerster** said that to-day, when medicine had become a positive science, cancer and pseudoleukæmia remained behind to teach us humility. He would not attempt to go into the pathology of the disease, but he firmly believed that it was of the nature of an infection. It was known that some cases run a rapidly fatal course whether treated or not, and that others run a very mild course. This explained the contradictions in the estimates of the various methods of treatment. He had been especially interested in the statement of Dr. Halsted regarding Dr. Reed's ability to distinguish Hodgkin's disease, even in the early stages, by the microscopical picture. This was more than any pathologist had hitherto claimed. The description of the rare and interesting case given in the paper reminded him of a series of cases reported by French observers under the title of "woody phlegmons." In them the lymphatic element was very prominent, especially the presence of the peculiar gelatinous substance mentioned by Dr. Halsted.

Dr. **B. Farquhar Curtis** said he was glad to hear that Dr. Halsted had been able to get some good results in operations on cases of Hodgkin's disease. When the diagnosis was certain, he, personally, did not feel like operating; when the diagnosis was uncertain, he sometimes extirpated large masses of glands, and then the pathologist was usually unable to make the diagnosis. Some of the cases diagnosticated as Hodgkin's disease certainly ran a rather benign course. He had been interested in the statements made by the reader of the paper regarding the adhesions of the glands to one another, because he had always supposed that these glands in Hodgkin's disease were easily separable.

Dr. **James Ewing** said it had been shown unquestionably that a very large proportion of the cases diagnosed clinically and regarded pathologically as Hodgkin's disease must be regarded now as tuberculosis of the lymph nodes. It had been long ago settled that there was nothing in the observed pathological changes in connection with Hodgkin's disease which could not be produced by tuberculosis. He did not believe that even ordinary inoculation experiments would be sufficient to exclude tuberculosis of the lymph nodes, nor did he think there was any good ground for believing that there existed cases of Hodgkin's disease upon which tuberculosis was engrafted. It was certain that other forms of infection than tuberculosis could lead to the same clinical history. This was well known to be the case with syphilis. However, the chief interest in the study of Hodgkin's disease seemed to determine whether there was any group of cases in which the lesions in the lymph nodes constituted a tumor process. The majority of surgeons and pathologists had excluded from Hodgkin's disease lymph sarcoma and certain of the inflammatory processes, notably tuberculosis, was about to be excluded. Whether or not there was such a tumor process was very difficult to determine. He believed this disease was on the border line between an inflammatory process and a tumor process.

Dr. Halsted said that, although tuberculosis was discovered in only one of their cases, it was not improbable that there was a larger number. He believed that tuberculosis was engrafted upon Hodgkin's disease. While they had great confidence in the microscopical diagnosis, they had not depended upon this altogether, and Dr. Reed's opinion had been reinforced by Drs. Welch, McCallum, and others. If Hodgkin's disease was an example of tuberculous infection, it was very different from other tuberculous infections of the glands, because Hodgkin's disease terminated fatally, while a considerable proportion of cases of tuberculosis of the glands of the neck were known to recover. Again, they had considerable faith in tuberculin, as it had never failed in their hands to give the characteristic reaction where the microscope showed tuberculosis. They always used the tuberculin obtained from Trudeau, and its administration was entrusted to one person, because it had been found that when an inexperienced observer undertook this work all sorts of errors crept in.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 22, 1902:

	Cases.	Deaths.
Measles	95	4
Diphtheria and croup	369	37
Scarlet fever	113	9
Smallpox	1	..
Varicella	65	..
Tuberculosis	258	149
Typhoid fever	115	28
Cerebrospinal meningitis	..	4

Does the Active Principle of Hæmolytic Sera Originate from the Mononuclear Leucocytes?—Paul Domeny, after a series of experimental studies, does not agree with Metchnikoff's view that the active principle of hæmolytic sera originates from the mononuclear leucocytes. In five out of six cases no hæmolytic power was possessed by washed leucocytes taken from the pleural exudate of specifically immunized animals. A comparison of the hæmolytic power of the blood plasma and serum shows that the action of the former, is as great as the latter and demonstrates that the active principle is present in the plasma previous to coagulation. In testing the hæmolytic action of the spleen extract of specifically immunized animals, it was found that such was present in an appreciable amount in only one out of thirteen cases.—*Wiener klinische Wochenschrift.*

The Prognosis of Suture of Nerves.—(1) The prognosis of nerve suture is very good; in physically strong persons and with regard to all precautions a good result is attainable from both primary and secondary suture, and in half of all cases the patient obtains a restoration of all function of the affected parts. (2) The result does not immediately appear, but requires a relatively long time for its complete development. The duration of the reparative process depends upon the two following factors: (*a*) the site of the injury and (*b*) the constitution of the patient. (3) A successful result does not follow in wide-spread injuries of the nerves, generally in irregular process of healing of the wound and in debilitated individuals, as well as in cases of cicatricial tissue at the site of the suture or around the sutured nerve.—P. Speiser in *Fortschritte der Medicin.*

Carnegie's Gift to the Nation.—*Science* has opened its pages to a discussion of the best manner of spending Mr. Carnegie's gift in the interests of scientific research. Among other suggestions made is the following, by Prof. E. B. Titchener of Cornell University: "In summary, then," the professor says, "I should advocate (1) increased facilities of scientific publication, and (2) scientific endowments of three kinds. These are: (1) The establishment of a few valuable fellowships; (2) The granting of a living wage for one year to men of promise; and (3) The unhampered gift of sums of money to men of scientific eminence—passed upon, perhaps, by a committee of their peers—on their personal guarantee to do with the gift what lies in their power to do for the advancement of science."

Bleeding at Stool in young children in the absence of symptoms of dysentery, is almost always caused by the presence of a polypus; rectal examination clears up the diagnosis.—*International Journal of Surgery.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended November 22, 1902:

OPERATIONS UPON THE UTERINE APPENDAGES FOR STERILITY.

By W. M. POLK, M.D.,
NEW YORK.

The restoration of function is always interesting, but when the function lacking is not only one that concerns the health of the individual, but surely and keenly touches happiness, and even domestic peace, its restoration has a claim upon our attention which warrants a wider attention than prevails toward the one I have in mind. The arts and sciences have solved the problem of feeding, warming, and clothing population. No matter how dense it may become normally, the doctrine of Malthus may therefore, be eliminated, and we may assert that, though individual convenience may conspire to produce sterility in women, no real necessity exists for it, provided it is not compelled by physical defects inherent to the individual, and assuming that prevailing social customs are not violated in testing it.

Any part of the female genital tract may be responsible for this condition, and enumeration of the conditions would include abnormalities as extended as the pathology of the several organs comprising it. Therefore, for brevity, we would only remind you that it is mainly due to obstructions in the channels of communication, extending from the ostium vaginæ to the ovary. Keeping to the appendages, we find that sterility so often depends upon their condition that we are prone to place in the sterile class nearly every woman whose appendages have once suffered decided inflammation. Many of these subjects undoubtedly recover this function, spontaneously as it were, improved local and general conditions developing quite independently of any medical or surgical aid. But many do not, even with such aid as up to the present time we have offered.

A glance at the state in which inflammation leaves such cases will sufficiently explain the reason. The appendages have lost their mobility and their position. The ovaries have usually a thickened covering, and contain, not infrequently, cysts. The tubes, besides being distorted, constricted, and displaced, are thickened, or perhaps thinned from distension, the distending element being mucopus, blood, or a clear serum. In many instances, however, there may be little beyond a minimum degree of distortion, some fine fibrillæ of organized adhesions and the fimbriæ more or less closed. When the more pronounced conditions prevail, symptoms are developed which, from the patient's point of view, take precedence of the sterility; but with most women they do not totally eclipse all anxiety upon that score. Lesser changes may give so few discomforts that the victim will be content to bear them; but if she be sterile also, the greater number will suffer concern upon that subject, and the degree of this concern will depend upon the necessity she may feel herself under to bear a child. The determining factors in this question are many, but they vary in urgency according to the desire or necessity for offspring. Each case, therefore, more perhaps than with any other abnormal state, must be dealt with upon its own merits. This brings me to the question outlined in the title of this paper. Shall we operate upon the uterine appendages primarily for the cure of sterility? Are we warranted in advising such a procedure for such a complaint? Is it too dangerous to be applied to a state which does not involve life? An answer, and perhaps a sufficient one, can be found in the history of operations for sterility done in the past upon other sections of the genital canal. Thirty years ago operations upon the uterus for the cure of sterility were common. I cannot lay my hands upon the statistics of such work, but no doubt your recollection will bear me out when I say that women then faced a mortality, in the the best hands, which placed the recognized operations upon the several parts of the uterus for sterility upon a footing with which the operations upon the appendages—essentially the same as that involved in my paper—compare favorably. In fact, I think I am within the truth if I assert that the mortality rate is even in favor of my proposition. I think, then, we can affirm that the operation upon the uterine appendages for the purpose in question is no more dangerous than was the accepted operation upon the uterus for that purpose thirty years ago. And if improved methods have practically stripped of mortality those operations, the one suggested can hope to reach the same perfection in perhaps the near future.

It is fortunate that my contention involves no new operative departure, for it simply advocates the extension of an accepted procedure to a single condition, which heretofore, when isolated, was not deemed grave enough to warrant it. Most operators bear in mind this function of the appendages, no matter what may be the reason for cutting down upon them, and take measures to restore it to them if compatible with safety. We argue merely for the extension of a principle.

The efficacy of the efforts expended upon the ovary to restore the function of child-bearing are sufficiently well-attested to indicate the line of action open to us, and in the light of what was thought possible to the tubes and ovaries a few years ago the results which have been already obtained are most encouraging. Shatz, for instance, as far back as 1880, left only one tube intact and a small section of ovary upon the corresponding side, and yet his patient married in 1884 and had a child in 1885 (*Centralblatt für Gynäkologie*, 1885, p. 353). The writer, in 1890, removed the right appendages and all of the infundibula of the left tube, leaving the corresponding ovary intact. The patient bore a child two years later. (*American Journal of Obstetrics*, Vol. XXIV, No. 9, 1891).

Baer of Philadelphia reports (*Annals of Gynecology and Pediatrics*, January, 1894, page 231–232) a case in which the uterus and appendages were bound down by adhesions. The appendages upon the left were removed entire; those upon the right, after having ben dissected from their adhesions, were in shreds, the tube having been torn off about two inches from the uterus. In the interest of child-bearing these mutilated structures were suffered to remain. Fifteen months later she gave birth to child.

MacMonagle of San Francisco reports a case even more remarkable, in which there was a pelvic abscess discharging by the rectum. When operated upon, the patient was septic, voiding pus and blood with stools every few days, and having an offensive purulent discharge from the uterus. This organ and its appendages were fixed in the pelvis by firm adhesions. Abdominal section revealed a condition of affairs in keeping with the signs and general symptoms presented. The right appendages were removed. The pus cavity, which had been discharging through the rectum, was connected with the left appendages, and the change which had been wrought by disease in the connections of these structures was such that although a ligature could be placed about them, to secure sufficient anchorage some portion of both had to be left in the stump. The ovarian vessels on both sides were ligated, and yet this woman, who had never been pregnant, although married several years before the operation, gave birth to a child three years after it. ("Transactions of the Congress of American Physicians and Surgeons," Vol. III, 1894, pp. 193-194).

Many other cases could be cited, but I will detain you with but two other reports: Ashby of Baltimore ("Transactions of the American Gynecological Society," Vol. XIX, 1894, p. 268) reported two cases. In one he merely freed the appendages from adhesions; in the other he did the same for one set of appendages, and removed the other. Both of these women conceived, the first having been previously sterile. She carried the child to term. The second aborted, which was properly attributed to the fact that the uterus became fixed in retroversion. Subsequently he again opened the abdomen and fixed the uterus forward by ventral attachment. The subsequent history of this case has not come to my notice.

Four years ago a patient, previously sterile, was operated upon by me for the avowed purpose of correcting this condition. The left appendages were freed from adhesions and the right in part removed. This was done because the right tube had become a hydrosalpinx and the ovary cystic. Two years later she gave birth to a child.

I might say much concerning the kind of operation which should be done upon the appendages for the cure of sterility, but the cases cited indicate the direction our efforts should take. The mere freeing of these organs from adhesions, so as to restore them as far as possible to their normal position and direction, seems all that is needed in many instances, care being taken to open up the fimbriated ends when they are closed or partially closed. But if pyosalpinx, hydrosalpinx, or hæmatosalpinx be present, then it seems proper to remove all the dilated portion, leaving the cut end of the tube free. The mucous membrane of the tube in such cases always protrudes, a fact which no doubt accounts for the continued patency which prevailed in the cases cited above. In such cases as become pregnant in spite of the only remaining tube being ligated, it is evident that the ligature cut through the tube, leaving the uterine end open—as much open, in fact, as if it had been left so by design. Some operators stitch the open infundibula to the surface of the ovary, but this hardly seems necessary if the normal connections between these organs are intact. If not, then the cut end of the tube must be brought close to the ovary by shortening the mesosalpinx. Everting the opened end of the tube and stitching the lining membrane to the outer surface seems necessary when any part of the infundibulum is to remain, or when the fimbriæ have been destroyed. When the entire infundibulum is removed, the pouting of the lining membrane appears to be sufficient to insure patency, but even if it should not be, the surface is too minute to tolerate the added irritation of a suture.

In dealing with the ovaries it is sufficient to act upon the principle that as much normal ovarian tissue is to be left as diseased conditions will warrant. Just here it is pertinent to say that, so far we are unable to determine in all cases the appearances which indicate the certain subsequent development of the more serious diseases of this organ, such as papilloma or large cysts. When this can be attained our choice of action in dealing with ovarian tissue will be more definite. At present I am inclined to give the ovary the benefit of the doubt. If the uterus is displaced backward it must be approximated to its normal position by some one of the operations practised for that purpose, my preference being for that which shortens the round ligaments within the abdominal cavity.

This paper, however, will fall short of its purpose if I fail to bring clearly before you the fact that it is designed to draw attention to that class of cases in which *sterility is the leading complaint, perhaps the only one the patient considers*, and in which our best endeavors show that the difficulty lies in the condition of the appendages. I am aware of the difficulties which beset conclusions in these cases, and of the painstaking investigation to be carried out with the two parties concerned; but acting along these lines, a correct conclusion can be reached, even though it involve the comparatively harmless measure of a preliminary vaginal incision for actual palpation of the suspected organs.

SPINAL-CORD TUMORS—TUMORS OF THE CENTRAL NERVOUS SYSTEM: REMARKS ON NOTEWORTHY CASES.*

By JOSEPH COLLINS, M.D.,
NEW YORK,

PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE POST-GRADUATE MEDICAL SCHOOL; PHYSICIAN TO THE CITY HOSPITAL.

Part I of this paper was published in the Medical Record, February 15, 1902, and was devoted to a study of brain tumors. I now propose to discuss some noteworthy cases, and briefly to review the present status of the treatment of spinal-cord tumors.

Tumors of the spinal cord offer a more tempting field for the surgeon than those of the brain, and they are encountered with less dread and feeling of helplessness by the neurologist. It is only fifteen years since Gowers and Horsley showed, by the publication of a properly diagnosticated and successfully operated case, that spinal-cord tumors might be treated successfully. Since then many cases have been operated upon, and with what result is shown in the table appended to this article.

Spinal-cord tumors are more susceptible to surgical treatment than brain tumors, and a greater percentage of recovery results from operative interference. Nevertheless the majority of spinal-cord tumors prove fatal, and must continue to do so for three reasons: (1) inability to diagnosticate and localize them, (2) the nature and extent of their growth which makes them inaccessible or inoperable, and (3) because of the jeopardy to life that the operation brings. With these limitations, the future of the successful treatment of spinal-cord tumors lies largely with the physician and with the surgeon. That the patient is not always a negligible quantity in the matter is shown by my first case.

---

*Read before the Neurological Society, November 4, 1902.

Spinal-cord tumor must be rare in comparison with brain tumors. Still the subject has an extensive literature. This is partly due to the fact that their surgical treatment has in latter years attracted much attention.

The diagnosis of spinal-cord tumor is much more difficult than that of brain tumor. The latter causes a clinical picture that is fairly constant and very characteristic. The former does not, particularly in its early stages. They may both exist without causing symptoms, but usually the smallest spinal-cord tumor produces very striking symptoms, while some brain tumors produce very few. The symptoms of spinal-cord tumor depend upon compression of the cord and roots and vary not only in character, but in kind, with the location of the tumor, *i. e.* upon the nerve matter that it encroaches upon. Therefore, symptoms vary with the size, the location, and the consistency of the growth. The part of the body to which the symptoms are referred, or wherein they are manifest, will depend upon the level of the tumor. For instance, the character of the symptoms may be the same whether the cervical, the dorsal, or the lumbar cord is involved, but the parts of the body wherein the symptoms are manifest will vary.

The term tumor of the spinal cord has come to have a generic meaning. In the ordinary usage of the term it means any tumor, and of any kind, that encroaches upon the spinal cord and so interferes with it functionally and anatomically. The tumor may arise from the vertebræ, the membranes of the cord, the dura and pia, or from the cord itself. The symptoms which tumor developing from each one of these different tissues produces vary somewhat with the original seat of the disease, especially the early symptoms, but, in the main, symptoms attending tumor developing from any of these parts are similar and depend upon irritation of the cord roots and pressure upon the cord itself. It is of much importance to distinguish extradural, intradural, and intramedullary growths, *i. e.* growths outside of the dura, between the dura and the cord, and of the cord itself. Occasionally this differentiation can be made with some degree of positiveness, but oftener it can only be approximated. Much more important than the diagnosis of the origin of the tumor is the diagnosis of the tumor itself. Until recently it has been supposed that intramedullary tumors were wholly unamenable to surgical procedure. Recently Abbe has published a case in which this was done successfully. It may, however, still be said that they are virtually beyond surgical aid.

The nature and the variety of the tumor are, from a clinical standpoint, of very little importance, because the most benign can produce just as much compression and lymph stasis as the most malignant.

The Symptoms of Spinal-Cord Tumor.—The symptoms of spinal-cord tumor, named in order of their customary development, are sensory, motor, visceral and trophic, and topical. The sensory symptoms are pain, often of a more or less typical kind, which will be discussed later, paræsthesia, and disturbance of pain, temperature and tactile sensibility of different degrees of intensity. The motor symptoms are spasticity, involuntary twitchings of muscles, and drawing up of the extremities, painful cramp of muscles, paralysis, in the early stages often of a spastic type, but becoming flaccid before the end, and increase of myotatic irritability manifested clinically by exaggerated tendon jerks, involuntary clonus of the foot (spinal epilepsy), etc. The visceral symptoms are referable principally to the bladder and depend upon the level of the cord implicated. If the tumor is of the lumbar or sacral regions of the cord, bladder symptoms usually develop early, and are accompanied by cessation of activity of the lower bowel. When the tumor is above the lumbar region, voluntary control of the bladder is lost as soon as a certain degree of cord compression has been reached; the rectal sphincter remains subservient to voluntary control in these cases longer than the vesical, but eventually it acts automatically. Priapism is said by some writers, Starr amongst others, to be common. So far as I may be entitled to an opinion from experience and from reviewing the literature, I should say it was not common. The trophic symptoms are muscular atrophy and bed-sores. They are both late manifestations. As a rule, in some instances in which a meningeal tumor is situated anteriorly and compresses the ventral part of the cord and the anterior roots, atrophy of the muscles is an early symptom. Bed-sores rarely develop until late in the disease, except in some cases of rapidly-growing intramedullary tumors. In a few instances, however, they develop earlier, as in case No. 2 reported herewith: The topical symptoms are tenderness on pressure over the spinous process beneath which the tumor lies and some deformity of the spinal column. The first seems to be a fairly constant accompaniment of spinal-cord tumor, the second an inconstant one of little diagnostic importance. In addition to these, there is sometimes stiffness of the spinal column and often disagreeable sensation in the back when the body is jarred by coughing or sneezing.

The clinical manifestations of spinal-cord tumors are, however, as I have said before, inconstant, and in a measure they depend upon whether the tumor is intra- or extramedullary. The two most difficult things in the diagnosis of spinal cord are to determine: (1) where the tumor is in relation to the surrounding structures, *i. e.* is it intra- or extradural, and (2) at what segment of the spinal cord is it situated?

In intramedullary tumors paraplegia is usually not so complete, though it may develop early with tumor of the meninges, but the great point in the diagnosis between the two is the pain, which in intramedullary tumor is rarely an initial symptom but it is almost invariably so in tumor of the meninges, and is of great severity. The next most important symptom in favor of extramedullary situation of the tumor is the limitation of the motor phenomena, in the beginning to one side of the body, such as an extremity or the predominance of paresis on one side of the body. The most important aid in determining to what segment of the cord the tumor is located is obtained from a study of the anæsthesia. The segmental relationship of the cord to the periphery of the body has been carefully mapped out, but that it is not as yet entirely satisfactory is shown by a number of cases in which the tumor has been found at a level above or below that to which the symptoms, particularly anæsthesia, pointed. In order to determine the location of the tumor in any given case it is necessary to make out carefully the limits of the anæsthesia, and the muscles that are paralyzed, and then to locate these functions by the aid of schemata or tables, in which the functions of the segments are tabulated, to be found in every textbook of nervous diseases.

The recent experiences of Starr, Oppenheim, and Schlesinger have shown that there is danger of localizing the tumor one segment too low, so that in every case of spinal-cord tumor that is submitted to operation the opening should be made over the upper end of the tumor, and if not found, a further opening should be made in an upward rather than in a downward direction. There are instances in which the tumor has been found lower than the symptoms seemed to indicate, but the autopsy has shown that the segment above the cord has undergone profound softening, as in a case reported by Schlesinger.

The consensus of opinion seems to be that the location of any tumor in the cord is from two to four inches above the uppermost limits of the anæsthesia, and more often the latter figure than the former. The question how many segments of the spinal cord are concerned in supplying any given tegumental area with sensory fibers is not settled. Sherrington, from experimental investigations, believes that three continuous areas are thus concerned, while Bruns, Schlesinger, and others are inclined to the belief that there are five continuous segments. Experience with tumors of the spinal cord inclines one to the latter view.

The importance of spinal sensitiveness as an aid in localizing the tumor is very considerable, especially if it coincides with the location which the sensory and motor phenomena indicate to be the seat of the disease.

In attempting to size up pain as a localizing factor in spinal-cord tumor, we are often confused by the wide-spread area over which the pain exists. It is not often that the pain confines itself to one or two roots. In some instances, however, the distribution of the pain is very suggestive of the location of the tumor, as in case No. 1 of my series, and also in Fraenkel's case. When the pain is diffused over large areas we must endeavor to harmonize its distribution with the other localizing symptoms.

The most common, as well as the most important, tumors of the spinal cord, using the term in its generic sense, are tumors of the meninges, especially tumors of the dura.

Those growing within the dura are nearly twice as common as those growing without. Extradural tumors may exist for a long time without giving rise to symptoms pointing to implication of the spinal cord, while intradural tumors give rise to such symptoms very early.

The favorite location for spinal-cord tumor is in the dorsal region, the lower and the upper end. In the seventy cases analyzed in this paper, thirty-five were of the dorsal region, fifteen of the cervical, thirteen of the lumbar and sacral, and six of wide-spread distribution.

Before discussing some of the more important questions in the diagnosis and treatment of spinal-cord tumors, and reviewing the recent literature, I shall relate the histories of three cases:

Case 1.—P. K., forty years old, married, by occupation a salesman, was seen with his physician, Dr. R. A. Shufelt, September 19, 1901, and the following history obtained. He married when twenty-five years old and has always been quite well. He denied venereal disease, and he has no recollection of ever having been injured save a fall from a bicycle seven years before, which was of no consequence. About two years ago he went into the cellar one morning, to look after the furnace, and, after having bent over to shake down the grate, he was taken with a "crick" in the back, and could not assume the erect posture. He crawled upstairs, and after a while the pain grew less, and he was able to straighten up a little more; but he had to be careful how he moved around for the next few days. From time to time this symptom recurred, but never so severely as at first, and under just what auspices he cannot say.

During the winter of 1901 he had a great deal of pain in the epigastrium and abdomen, which he attributed to indigestion, particularly to the accumulation of gas; this pain was colicky in character and might last several days. It was made worse by jarring of the body and relieved by free movement of the bowels. Later the attacks occurred more frequent and lasted longer. During one of these attacks the pain was more or less circumscribed to the right mid-abdominal region, and it was thought by the physician who saw him that an impaction of the colon existed. At another time the diagnosis of appendicitis was made, and an operation advised.

In June, 1901, that is four months before I was asked to see him, a new group of symptoms developed, consisting of stiffness of the leg, which he noticed first after having sat for a length of time. At first this stiffness was very slight, but it has increased steadily, until now he is stiff all the time. He maintains that it is worse when he has the symptoms which he calls indigestion, *i. e.* pain in the abdomen, feeling of distension and constipation. When he is free from these he says the stiffness of the legs is very much less. Soon after leg weariness showed itself. The legs would get very tired during the afternoon, and by the time he reached his home in the suburbs toward evening he was glad to lie down. This leg weariness increased to weakness, the left leg being weaker than the right. About this time he began to get very nervous, and he remarked that he was losing flesh continually. No paræsthesia or pains in the legs. No stiffness or pain in back and no pain in the spine upon movement. Latterly involuntary twitching of the leg, particularly of the left, has developed. Sometimes the left heel beats a tattoo on the floor when the toes only are in contact.

Examination reveals moderately spastic gait. No disturbance of station. He can stand on either foot. The left lower extremity is weaker than the right. The tendon jerks of the lower extremities are exaggerated more on the left side than on the right. The plantar reflexes are lively, but of a normal type. The cremasteric is elicitable and the abdominal absent. Kernig's sign is elicitable most typically. The right lower extremity is analgesic, extending upward as far as the level of the umbilicus. Tactile sensibility is preserved. Thermal sensibility is blunted in the right lower extremity, but by no means absent. The left lower extremity is slightly analgesic, not more so in one area than another. Tactile sensibility is preserved.

There is no tenderness or prominence of any part of the spinal column.

A diagnosis of spinal-cord tumor was made, and localized to the tenth or eleventh dorsal segments of the cord, probably to the right of the median line. The patient was the subject of a clinical lecture on spinal-cord tumor, at the Post-Graduate School, on October 3, and he was urged to enter the hospital for operation. He consented in a measure, but while waiting to go into the hospital he encountered a malign influence in the shape of some one who promised him relief from medical treatment. I did not hear from him until ten months later, when Dr. Shufelt, whose counsel he had forsaken, told me of his pitiful condition, and asked that he be taken into the hospital. This was done, and as I left town the following day for a considerable absence, I asked my chief of clinic, Dr. Abrahamson, to take charge of him, which he did. He has kindly given me the notes of the examination made at that time:

The patient has had no pain since February, 1902, nor has he been able to get about since then, and now he can not rise to a sitting position without assistance. During the past few months there has been slight trouble in starting the urine. Lower spine presents slight backward curvature. From time to time, upon raising lower extremities, an exceedingly rapid clonus results. The legs are completely extended; slight extension of the feet; moderate plantar flexion of the soles. Dorsal flexion of both great toes, and of the first phalanges of the other toes. Clasp-knife rigidity of the lower extremities. Strumpell phenomenon elicitable. Knee and ankle-jerks very much exaggerated; patellar and ankle clonus. Babinski phenomenon on both sides. Some œdema of both feet and legs. Slight wasting of the quadriceps muscle, especially of the left and of the peronei. Weakness of the abdominal muscles of both sides. During the past three months the legs draw up by day and by night, at times spasmodically; legs are extended and flexed alternately. Epigastric reflex present, abdominal reflex absent, cremasteric reflex lively. Sensory disturbances. Analgesia on the posterior surface of the body and legs reaching up to the twelfth dorsal vertebræ, more pronounced on the right side than on the left. Temperature sense lost on the posterior surface as high as the first lumbar; tactile sense as high as the twelfth rib, with the exception of a slight area over the buttock. On the anterior surface there is analgesia downward from a line drawn from one inch below the sternum around the ninth to the tenth rib. Anæsthesia for heat over practically the same area. He has lost the capacity to detect cold on the anterior surface of the body and leg of the right side only. There is no anæsthesia to cold over the anterior surface of the left leg. Tactile sensibility is obtunded from the eighth rib downward, but it is not lost, for he can feel whenever the touch is heavy.

The operation was done by Dr. Samuel Lloyd.

Incision from the fourth to the ninth dorsal spinous processes. Muscles separated from the spinous processes and raised from the laminæ with periosteotome from the fifth to the eighth dorsal vertebræ, divided at these junctions with laminæ with bone forceps. The laminea of the fifth to the eighth dorsal removed with rongeur forceps, laying bare the groove in the dura. When the dura was split longitudinally the tumor was exposed. The tumor was firmly attached to the dura on the inner surface. This was removed by a curette and spoon, aided by the finger. It was about 1½ cm. in length, 1 cm. in breadth, right over the oval; microscopically, it appeared to be sarcoma.

The operation was done without very much difficulty. The results of the operation are not brilliant, but this is accounted for by the fact that the lesion had caused irreparable destruction in the cord. The patient's present condition is indicated by the following record of an examination made a few days ago:

There is some movement of the toes of the left foot and in the foot itself. Slight movement of the toes of the right foot, but less so than the left. Some power of the lower extremities, taken as a whole, but owing to the stiffness this is not exactly ascertainable. Sensibility of the left side is much less perverted than before. Pain is now felt acutely all over, temperature ditto, although there are slight areas of diminished sensation on the right side. The function of the bladder is now nearly normal, save for a slight hitch at times in urination. Rectal sphincter normal. No pain, no feeble sensation. Feels very well otherwise. Is resistant to passive movements on both sides. Clasp-knife rigidity less evident. Knee-jerks and ankle-jerks are very lively. Ankle clonus and Babinski phenomenon both present.

The diagnosis of tumor was made about a year before the operation was finally consented to. If the tumor had been removed at that time there can be no question but that the patient would have wholly recovered. He was then able to discharge his duty as a clerk, which necessitated being on his feet almost the entire day. The diagnosis at that time was based upon (1) the character and location of the pain, its paroxysmalness in the abdomen, particularly the epigastric and umbilical region and its peculiar relationship to the motor symptoms. (2) Motor weakness beginning in one extremity and gradually increasing, later affecting the other lower extremity, and of the spastic type. (3) The phenomena constituting the Brown-Sequard syndrome. (4) The course of the disease, gradually progressive. (5) By exclusion. Such an association of symptoms could scarcely be caused by anything but a tumor.

Symptoms that bespoke the localization of the tumor were not very definite, but assuming that the seat of the tumor is, as a rule, from four to five inches above the level of the sensory disturbances, taken in connection with the motor paralysis and the location of the pain, the tenth thoracic segment or thereabout seemed to be the site in this case.

The following facts bespoke an extramedullary growth: (1) The pain preceded the motor symptoms by from one to two years. Occasionally pain precedes motor symptoms in intramedullary tumors, as in Abbes's case, but it is the exception to the rule. (2) The motor symptoms came gradually; they were first of one side, and were not accompanied by atrophy. Not that the motor symptoms always develop in this way when the tumor is of the meninges. For instance, in Strube's case, a dural tumor, motor symptoms developed very suddenly, and were soon followed by œdema and decubitus. (3) The absence of vasomotor symptoms. (4) The Brown-Sequard syndrome.

Pain is one of the most important symptoms in spinal-cord tumor. In only 10 per cent. of the cases is it absent. In upward of 50 per cent. it is what is called characteristic, *i. e.* of a lancinating neuralgic character of some part of the trunk or the extremities. Like neuralgia, it is rarely continuous, but, unlike it, it is not associated with sensitiveness to pressure of the nerve trunks. In the cases that I have collected from the literature it was absent only five times.

Pain in the abdomen caused by interspinal tumors is not typical. It is often thought by the patient and physician to be dependent upon some local condition. In my patient it was diagnosticated as dependent upon appendicitis. Dr. Fraenkel's patient had had the appendix removed; one of Schultze's cases was treated for gallstone colic, one of Putnam's for indigestion, and one of Starr's for angina pectoris. A knowledge of this should make us very keen to search out the real cause of abdominal or thoracic pain, and it should constantly remind us that when such pain is associated with objective sensory or motor disturbances referable to one or more of the extremities that the chances are very much in favor of its being dependent upon the spinal-cord tumor.

Abdominal pain is all the more readily mistaken for some visceral disease, because of its apparent relationship to eating, flatulency, and constipation.

This relationship has often been noted (Laquer, Ransom & Thompson, Putnam & Warren, *et al*). In my case the patient was positive that the motor symptoms, spasticity and unwieldiness of the legs, were very much worse when the bowels were flatulent or constipated. In the early stages of his illness he always felt better after having taken calomel and dieted. I see no reason for attempting further explanation of this variety of pain than that which suffices for other forms of pain occurring with spinal-cord tumor. It is due to irritation of the affected segments of the spinal cord. When the bowel is sluggish or distended that constitutes an additional irritation of the affected segments.

CASE II.—L. L., a Hungarian girl, nineteen years old, was admitted to the City Hospital in December, 1899.

When she was ten years old she had an attack of pneumonia, which left her in a feeble condition, and with a cough for a number of months. After this she was quite well until December, 1898. At this time she was taken ill with indefinite symptoms and menorrhagia, which lasted off and on for six weeks, during which time she became so weak that she was unable to walk without assistance. She entered the Lebanon hospital, where, she says, she was treated for pneumonia, and was in bed for six weeks. During this illness urine had to be drawn by the catheter, and the bowels moved by enemata. At the end of this time when she got out of bed she was not able to walk. Her legs were heavy, cold, and powerless, and when she attempted to walk with assistance she could scarcely drag them over the floor. Both hands were contracted, the left more than the right, so that she could not grasp objects. She remained in the hospital five weeks longer, during which time she became able to walk and to use her hands a little. She says, however, that she was never able to stand erect and walk as well after this illness. During the remainder of the winter and the spring she grew weaker and thinner, but she was able to get about. When summer came she regained to a considerable extent the use of her arms, but her state was not satisfactory, and she went to the Mount Sinai Hospital, where she remained for two months. She says a plaster jacket was made for her; after she left there she wore it for one night only, because the next day, when she attempted to get up, she found that she was unable to walk. The paraplegia continued to increase, and it was quite complete when she came into the City Hospital. Examination at this time showed spastic paraplegia, the spasticity, however, was not very profound; loss of strength, and increased resistance to passive movements of the upper extremities, the left more than the right; increased tendon jerks, especially the knee and ankle jerks; plantar jerks present, of the flexor type; abdominal reflex absent; inability to retain the urine and constipation. Examination of the sensory sphere showed a degree of blunted sensibility in the four extremities, more in the legs than in the arms, but nothing approaching anæsthesia or analgesia. The patient complained of pain in the back without definite localization.

The case was diagnosticated as one of myelitis, following pneumonia, and very little medical attention was given to it. During the winter she became very much emaciated, profoundly anæmic, and developed bed-sores on the left heel, leg, knee, trochanter, and over the sacrum. Four months before she died she was transferred to the Montefiore Home, and I am indebted to Dr. Fraenkel for a transcript of the notes of the autopsy. Only those relating to the spinal cord will be used here.

On opening the spinal canal there is seen in the cervical region a soft, yellowish tumor mass wedged in between the bodies of the vertebræ and the dura. This tumor extends from midway between the third and fourth cervical to the level of the first dorsal. Its posterior surface can easily be separated from the dura. Its anterior part was attached to, but does not penetrate, the dura, being entirely extradural. It compresses the cord, but does not invade the substance. Below the lesion the cord is firm. So far as may be judged from the appearance of the greatest growth of the tumor, it originated at about the level of the fifth cervical vertebræ. (Fig. 1). The nature of the tumor was a spindle-cell sarcoma.

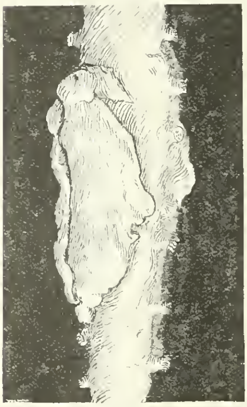

FIG I

This case should, in reality, have been diagnosticated as a spinal-cord tumor. We were misled by the history of her illness. Her symptoms seemed to grow out of an attack of pneumonia, and having in mind the relationship of pneumonia to myelitis, and impressed with the fact that the symptoms were those of myelitis, that diagnosis was made. As a matter of fact, the autopsy showed that the patient had not had pneumonia in December, 1898, or, at least, if she had, every vestige of it had disappeared. The symptoms which the patient had when pneumonia was diagnosticated were, probably, pain in the chest, weakness, and dyspnœa, symptoms which may easily be attributed to the tumor.

The tumor could have been removed, but the nature of the growth would have precluded any permanent benefit from operation.

CASE III.—D. H., an unmarried negress, twenty-three years old, was admitted to the City Hospital on the 13th of September, 1898. She was carried in on a stretcher, and although evidently extremely ill and suffering great pain, she was in full possession of her mind, and gave the following history of the development of the disease: On the 29th of August, 1898, *i. e.* just two weeks before her entrance into the hospital, and practically the same length of time before her death, for she succumbed on the 15th of September, 1898, she noticed, while at work, as a domestic, a subjective feeling of numbness and loss of power in both legs. The latter increased rapidly, so that five days later she was completely paraplegic, the paralysis extending, she said, as far as the middle of the body. She maintained that before the 29th of August she had had no difficulty in passing or retaining urine and no incontinency of the rectal sphincter, but, beginning on that date, there was retention of urine, which necessitated catheterization regularly, and incontinence of fæces. Until the day of her admission, September 13, the retention continued, but on that date she became incontinent. A few days after the onset of the subjective sensation of numbness and loss of power in the legs, she complained of a sensation of formication in the lower extremities, and of burning feelings and drawing sensation in the hips. Aside from this she made no complaint of pain. On inquiring into her history, it was found that she had never menstruated, but since the age of fifteen she had had, at regular intervals of four weeks, attacks of pelvic pain, vomiting, headache, and malaise, which lasted for from three to four days, and that for some time past, possibly two or three years, but especially during 1897 she had noticed a gradual increase of size of the hypogastric region. There was no complaint of pain or of loss of flesh at this time. Examination by Dr. George M. Tuttle showed that the region from the umbilicus downward to the symphysis gave a peculiar resistant and irregular feeling, comparable to that obtained by pressing the hand upon a sack of potatoes. The mass was somewhat movable from side to side, and not tender. It could be distinctly made out that the surface of the large nodules was broken up by small irregularities. Ocular, digital, and bimanual examinations revealed normal conditions, save an infantile uterus. The cervix was freely movable, apart from the mass, but no uterine body could be felt above the surface.

On April 4, 1898, a complete abdominal hysterectomy was performed, and an examination of the organs and tissues removed showed a tumor of the left ovary, nodular, having a circumference of 51 centimeters. In certain areas it was decidedly cystic. The right ovary presented a very similar appearance, and was about as large as a hen's egg. The right tube was normal, save in size. It was extremely infantile. The left tube was drawn over the surface of the ovary, on which it lay in a groove, and was normal in appearance. The uterus appeared as a slender cord between the layers of the broad ligament. It measured five centimeters from the surface to the fundus. Infantile in appearance, there was yet no atresia in any part of the canal. A microscopical examination of the tumor showed that its nature was that of an endothelioma. After her discharge from the hospital she returned to her occupation as a domestic and kept to it until the date mentioned above. On repeated inquiries she finally admits that in July, 1898, she had some pain in the knees which she called rheumatism. It was not sufficient to compel her to forego work, and soon disappeared without treatment.

Examination showed an extremely emaciated woman, whose features are expressive of great suffering. She lies on the left side, the legs and thighs being semiflexed, while the trunk and upper extremities have a fixed expression. She cries out in fear when the bedclothes are laid back, and says that every movement, or attempt at movement, of the body hurts her back. There is a bedsore about the size of the hand over the sacrum, the duration of which she is unable to state. There are no other trophic changes save symmetrically-arranged scars over the shins, the relics of ancient ulceration. When questioned about these she says she had sore legs five years ago. The extremities are cold, the respirations shallow, and the features drawn and pinched. When the lower extremities are moved she complains of great pain in the back. She is seemingly unable to make any voluntary movement of the lower extremities. The paraplegia cannot be truthfully called flaccid, for there is some slight resistance to passive movement. There is complete loss of sensibility, touch, temperature and painful stimuli in the lower extremities extending on the right side to midway between the level of the crest of the ilium and the anterior inferior spine. On the left side it extends about two and one-half inches higher, both in front and behind. The areas of sensory loss are shown by the accompanying diagrams, and at the time of examination. The most careful examination failed to reveal any cutaneous surface of the lower extremities but to [illegible] regions in which sensory stimuli were perceived. There is local elevation of temperature of 1½° F. over the abdomen below the umbilicus and immediately around the umbilicus. Palpation of the abdomen reveals a nodular mass in the upper part of the left side. It extends through the entire left abdominal region as far down as the umbilicus, and toward the right the area of dulness blends with that of the liver. It is irregular to the touch and wholly immovable. The knee jerks and all the superficial reflexes of the lower extremities are absent. When the patient is turned on the side it is noted that the back is fixed rigidly, and that the lumbar region is somewhat arched. The spines of the seventh and eighth dorsal vertebræ are prominent, and she cries out with pain when they, as well as the spine of the ninth dorsal vertebra, are subjected to pressure. The upper extremities are freely movable, both actively and passively, but she restrains from using them on account of pain in the back that such movement causes. The cranial nerves are uninvolved, and there are no sensory disturbances of the upper part of the body. Although it is not easy to detect vasomotor phenomena in a colored person, this patient did not present any unless the local elevation of surface temperature of the lower abdomen be thus construed. There was no œdema of any part of the body.

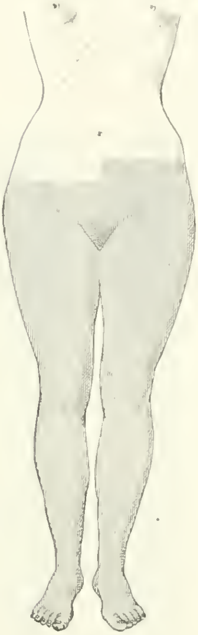

FIG. II.

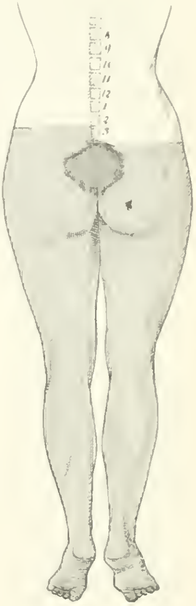

FIG. III.

The patient was at once put in a tub of warm water and preparations made to open the spinal canal at the site of greatest tenderness, viz., the ninth dorsal vertebra. It was late in the day when she was first examined, and it was impossible to secure the services of a surgeon until the following day, by which time she had fortunately been relieved by death.

The post-mortem examination was made on the following day, the spinal canal being opened first. When the posterior arch of the spinal column was removed, a reddish, soft-looking mass was seen lying over the posterior and lateral aspects of the cord, reaching from the ninth to the twelfth dorsal vertebræ, and covering the cord from the twelfth dorsal to the fourth lumbar segment. The somewhat sausage-shaped mass, 10 mm. long, broader below than above, in the substance and upon the meninges, was evidently intimately attached to the cord. In the lower portion it seemed to completely envelop the cord, and after the latter was lifted out it was seen that it was in connection with the intraabdominal growth by means of a very narrow tissue, which extended in between the laminæ of the vertebræ. The cord itself, although surrounded by the mass, did not seem to be very much compressed, nor was there any evidence of softening. The cord with the attached tumor was put at once in alcohol and the relationships of the tumor are to be seen in Fig. 4. It is very much shrunken from the preservative fluid, but its relative proportion and implications are still to be observed. It is seen to be in the substance of the pia, implicating the roots of the upper lumbar segments. The vertebræ were not diseased.

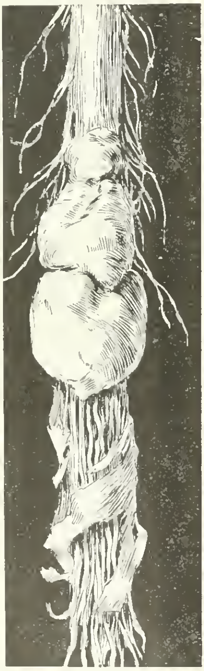

Fig IV.

When the thoracic cavity was opened the heart and lungs were found, in their normal positions, and when removed they were seen to be of normal constitution. A longitudinal scar was found in the median line, extending from the umbilicus to the symphysis. On opening the abdominal cavity it was found to be free from adhesions, the cavity of the pelvis containing coils of small intestines, but no uterus or adnexa. On removing the coils of intestines, a firm, immovable mass was found in the middle of the abdominal cavity between the second lumbar and tenth dorsal vertebræ, to the bodies of which it seemed to be attached. It was entirely retroperitoneal, and was covered in front by the pancreas and coils of intestines. The mesentery in the region of the growth contained many firm, whitish gray nodules about the size of a hickory nut. They were particularly numerous in the mesentery attached to the lesser curvature of the stomach. The walls of the hollow viscera and the substance of the solid viscera were not implicated by the growth. Upon tracing the course of the aorta and vena cava downward they were seen to pass through the tumor, disturbed in their normal relationship, but apparently patent. Examination of the dural tumor and of the abdominal tumor shows them to be of the same constitution, viz., that of a round-cell sarcoma.

The noteworthy features of this case are: (1) The sudden onset; (2) The simultaneous and complete overthrowal of the functions of the bladder and bowels; (3) Paraplegia dolorosa, the motor mechanism being potentially preserved; (4) Localized pain in the back; (5) Absence of radiating, neuralgic pain in the extremities; (6) The early occurrence of localized trophic symptoms, in the shape of a bedsore, closely localized.

Statistics of Spinal-Cord Tumors.—The statistics of operation for spinal-cord tumors have been gathered in this country by Mills and Lloyd ("Pepper's System of Medicine"); by Starr, (*American Journal of the Medical Sciences*, 1895); by Putnam & Warren (*American Journal of the Medical Sciences*, October, 1899); in England by Gowers and Horsley ("Transactions of the Medico-Chirrurgical Society of London," 1887), and in Germany by Bruns, in 1896, and in Austria by Schlesinger, in 1898.

I have gathered from the accessible literature the cases that have been published during the last six years. Brief abstracts of these are appended to this article.

The list does not purport to be complete, nevertheless it will be found to include most of the reported cases. A few published as inaugural theses in Germany could not be obtained, but, as some of these have probably been mentioned in discussions by others, they may be included in the list. My list includes but two of the cases (in addition to his own) in Putman's list of successfully operated cases, although his article was published in 1899, nor does it include such cases as that of Batten sarcomata, involving spinal cord, in a child three years old, growing from the vertebræ, the primary growth being in the thorax. Nor do I include congenital tumors, such as the remarkable case reported by Heurtaux (*Bulletin et memoires de la Société de Chirurgie de Paris*, vol. 24, p. 7,561) of an enormous fibroma on the side of the neck of intraspinal origin from the dura. I do not include in my list small intramedullary fibroma with syringomyelia, such as have been reported by Heverroch, Pick, Schlesinger, Raymond, *et al.* A few of the cases reported in my list are included in Schlesinger's monograph, but the vast majority of them have not heretofore been collated.

I quote the history of seventy cases. Surgical operation was undertaken in thirty cases.*

The results of the operation in these thirty cases were as follows: Successful in twelve instances, partially successful in eight, and wholly unsuccessful in ten cases. The operation was considered successful when there was cessation of pain and recovery of motor power; partially successful when there was relief from pain, cessation of progress of the case, and slight regain of motor power; unsuccessful when followed by a death within a few weeks. The nature of the tumor is not stated in the reports of all of the operated cases, but so far as could be determined there were six fibroma, twelve sarcoma of one kind or another, three endothelioma, and one myolipoma. Those cases that succumbed soon after the operation were made up largely of those in which the tumor was a sarcoma, although the patient with myolipoma died from sepsis. All of the cases in which the tumor was found to be a fibroma recovered with one exception, that of Starr, who also died of sepsis. The cause of death as given in nine of the cases that terminated fatally was sepsis and septic meningitis, four cases; collapse and exhaustion, two cases; shock and hemorrhage, two cases, and pneumonia, one case.

If we add to this list the fourteen cases which the autopsy records show might possibly have been successfully operated upon if the diagnosis had been made, we find that forty-four out of seventy cases of intraspinal tumors might have been treated surgically, *i. e.* forty-four cases were operable. This is an extremely high percentage in comparison with the operability of brain tumors. It is not so high, however, as that given by Starr, who was of the opinion in 1895 that 75 per cent. were operable. My own belief is that the operability of spinal cord tumors is considerably less than the percentage which my statistics seem to give. When we look into the record of the cases that are considered operable, we see that in a number of them not only the size and location of the tumor found post mortem, but their nature puts many of them in the list of inoperable. Of the fourteen cases ten were some variety of sarcoma three glioma, two endothelioma, and one psammoma. In reality there is none of the variety that surgeons have removed most successfully. On the other hand, the variety which is most frequently unsuccessful in the surgeons' hands, sarcoma, predominates. Although the neoplasms might have been removed, it does not at all follow that the operation would have been successful. In twenty-six cases the tumor was wholly beyond the scope of operation.

---

*These cases are the thirty histories in the beginning of the appended list.

That the operation for removal of spinal-cord tumor is however, fast growing in favor is shown by the number of instances in which it has been undertaken during the last five years. Starr stated in 1895 that he was able to find record of 123 cases, and in these operation had been undertaken twenty-two times, while in the seventy cases that I have collected it had been undertaken thirty times.

The Results of Operation for Spinal-Cord Tumor. —It is not an easy matter to answer the question, "What may be expected from operative interference in the treatment of interspinal tumors, *i. e.* What is the status of operative surgery in the treatment of these tumors?" If one were to base his opinion upon the published reports of Schultze, for instance, he might easily maintain that the surgical treatment of spinal-cord tumors was extremely successful; on the other hand, such an experience would be considered as evidence of good luck by another whose experience had been very different. Basing the statement upon the reports of cases operated upon, and those that have come to autopsy, without operation, it may be said that 50 per cent. of intraspinal tumors are operable, and of this number one-third to one-half are benefited by operation. Spinal-cord tumors are, therefore, twice as operable as brain tumors, and the results of operation are twice as successful. When the surgeon so perfects his technique that he can perform the operation for spinal-cord tumor without development of sepsis, the percentage of cases benefited by operation will be much greater. For instance, the cases reported by Oppenheim, Starr, and Fraenkel recovered from the operation, but they died from sepsis.

Schultze* has recently given a synopsis of eight cases of spinal-cord tumor. In two the diagnosis was erroneous, in the other six, all of which were operated upon, three recovered, two completely, and one partially. In two death followed the operation. In one of the cases in which death resulted there was a large tumor at the level of the cauda equina; in the second there was annular tumorous thickening of the dura, which could not be removed.

When one considers the hopelessness of these cases when treated medicinally, it will readily be seen that surgical interference is the only thing. The result of surgical treatment has been such as to encourage us in the belief that continuance of effort in the same direction will be followed by a greater degree of success. This view is probably generally accepted. The urgency in the treatment of these cases is that they be diagnosticated and operated upon early, *i. e.* before inflammatory, œdematous, anæmic, necrotic, or degenerative changes that are irreparable have gone on in the spinal cord. If the operation is delayed until these have occurred, the cord's activities cannot possibly be restored. Nothing is more pernicious, it seems to me, than delay after diagnosis of the tumor has been made, in order that medical treatment, particularly iodide or arsenic, may be tried. Gumma of the cord rarely produces the symptom complex of spinal-cord tumors, and if one should mistake occasionally a gumma for spinal-cord tumor and submit the patient to an operation, nothing possibly can be lost. The degree of recovery after operation will, of course, stand in direct relationship to the condition of the spinal cord, and this agrees rather constantly with the duration and intensity of the symptoms. If paraplegia has existed for several months, for instance, and if trophic symptoms of the skin and muscles have appeared, the surgeon may be able to remove the tumor, but all that can be expected by the patient is that the diease will stop progressing.

Another question that frequently arises after operation is, "To what degree may improvement be expected to result in a case that has not shown much results to the recovery of function in two or three months after the operation." To this question a negative reply must be given. Examination of the published cases shows that if improvement does not follow soon after the operation, it does not occur to any considerable degree at all. It must at once be added, however, that in many cases there is immediately after the operation an accession of paralytic phenomena which are not to be attributed to changes produced in the cord by the tumor itself, but are secondary to the trauma of the operation. These, as a rule, disappear.

Delay in operating is responsible for the slight beneficial results that have followed operation in some cases. This cannot be laid at the door of operation however. It is possible also that had some of the cases of sarcoma been operated upon early, *i. e.* before the tumor had reached such considerable growth, the outcome would be different.

Taking everything into consideration, it may be said that the surgical treatment of spinal-cord tumors offers the most attractive field for surgical interference of all diseases of the nervous system. Still a word must be said about the inadequacy of surgery in these cases. Patients nowadays die from sepsis after the operation about as frequently as they did ten years ago. The operation seems just as prolonged as it did formerly, and the loss of blood is oftentimes very great, and in some cases—flat sarcoma—not easily controlled. Until the surgeon overcomes some, or all of them, it can not be admitted that the majority of spinal-cord tumors can be operated upon with prospect of success.

ABSTRACTS OF SEVENTY CASES OF SPINAL-CORD TUMOR.

THE THIRTY FIRST ENUMERATED CASES WERE SUBMITTED TO OPERATION.

Fraenkel. *Journal of Nervous and Mental Diseases*, December, 1902.—Female, forty years old. Initial symptom, pain in right hypochondriac region; duration of pain, three years; later, pain in right buttock, then paræsthesias of perineum. At time of examination, paralysis and atrophy of right quadriceps and adductor muscles. Paresis of muscles of right leg and foot, and paralysis of muscles of left foot. Obstinate constipation, retention of urine, disturbances of sensibility over right half of buttock, perineum and vulva. Operation, tumor found between the strands of cauda equina to the left of the median line; nature of tumor, fibrosarcoma; improvement; death four months after operation.

---

*Versammlungen Südwest-Deutscher Neurologen, Baden-Baden, May, 1902.

Abrahamson, *Journal of Nervous and Mental Diseases*, December, 1902.—Male, sixty years old. Initial symptom, thermoparæsthesia in left and later in right foot, then increasing spastic weakness in right, later left lower extremities; still later atrophic, right-sided paralysis of upper extremities. Tardy appearance of objective sensory disturbances, even in the presence of very marked motor. Total paralysis of lower extremities; band of hyperæsthesia in right supraspinatus region; sensory disturbances two and one half years later of the entire cutaneous surface below third rib anteriorly and second dorsal spine posteriorly; vasomotor disturbances in hands, chiefly right; bladder and rectal involvement; dilatation of right pupil. Operation, a fibrosarcoma removed from the inner surface of the dura at the level of the seventh cervical segment. It had encroached upon the right antero-lateral surface of the cord. The patient died a month later of secondary septic infection.

Schultze, *Deutsche Zeitschrift fur Nervenheilkunde*, Vol. 16, p. 114.—Woman forty-nine years old. Initial symptoms; general nervousness and severe pain in the upper part of the back; pain radiated into the chest and the right arm, later pain in both eyes, forehead, and stomach. Diagnosis of gallstone was made. Later peculiar disagreeable feelings in the legs, paresis, and vesical symptoms; spastic paraplegia, loss of sensibility for touch and pain in the legs, increase of bladder symptoms, severe pain and involuntary muscular contraction in the legs and abdomen; tenderness of the tenth dorsal vertebra, increase of the tendon jerks of the lower extremities; duration, eight years; operation, removal of the spinous processes of the fourth and fifth dorsal vertebræ; removal of a tumor 4 cm. long, 2½ cm. wide behind and outside the dura; recovery.

Case II.—Man twenty-eight years old. Initial symptom, increasing weakness of the leg and paræsthesia, no pain at this time, but had had neuralgia of several years' duration in the right side and in the leg. Paræsthesia first in the right leg afterward in the left, and thermoanæsthesia and slight analgesia in the loins and legs, sphincter disturbances; progressive spastic paraplegia; operation over the sixth and seventh dorsal vertebræ. After opening the dura the tumor was found and removed; fibrosarcoma; duration of the paralysis, four months; recovery.

Schultze has recently spoken of the results of four more cases that had been submitted to operation, which are referred to in the text.

Boettiger, *Archiv für Psychiatrie*, Vol. 35, No. 1, p. 83.—Female, sixty-three years old. Initial symptoms, weakness and paræsthesia in right lower extremity; burning and tension in right lower part of trunk; affection of temperature and pain sensibility in right lower limb; Brown-Sequard syndrome, motor symptoms appeared before sensory; later, paralysis of right lower limb and right lower abdominal muscles; right patellar reflex exaggerated, and right ankle clonus; operation, removal of psammoma eighth thoracic segment; recovery; partial regain of motor functions.

Krause, *Berliner klinische Wochenschrift*, 1901, No. 20-22.—Woman, sixty-five years old. Initial symptom, weakness of the right knee, later paræsthesia of the right thigh and of the right sole; later extension into the left leg, girdle feeling, weakness of the right leg, and finally complete paralysis; hypalgesia of the left lower extremity (Brown-Sequard symptom complex); disturbance of the bladder and bowels; sensibility of the right lower extremity normal, save between sacrum and major trochanter, which was anæsthetic; left lower extremity completely anæsthetic; patellar reflex normal, achilles reflex exaggerated; operation, resection of the eighth and ninth dorsal vertebræ. The tumor was found beneath the seventh and sixth; the size of a hazel nut; easily detached from the pia, but the dura had to be removed with it; recovery.

Remak, *Neurologisches Centralblat*, 1902, p. 621.—Woman, twenty years old. Initial symptoms, severe left-sided sciatica, followed by gradual paralysis of the leg, especially of the gluteal and peroneal hyperæsthesia of the left leg, loss of the patellar reflex, slight sensibility disturbance of the left thigh, transitory disturbance of the bladder, tenderness over the small of the back; diagnosis, tumor of the cauda equina; operation, opening of the fifth lumbar vertebra; intradural tumor extended further upward than was anticipated, and it was impossible to remove it, although the fourth and third vertebræ were opened; exitus in collapse twenty-four hours afterward. Autopsy showed the entire lumbar cord surrounded with sarcomatous masses.

Sachs, *Journal of Nervous and Mental Diseases*, Vol. 27, 1900, p. 108.—Man, fifty-six years old. Initial symptom, pain in the lower extremity, later spasm of the muscles; tenderness over the second lumbar vertebra; diminution of tactile, pain, and temperature sense at the upper and inner portion of the right thigh; right knee-jerk absent; removal of the spinous processes of the lumbar vertebra showed an alveolar sarcoma the size of a small cherry adherent to the dura and bone; recovery.

Case II.—Man, thirty-nine years old. Had been diagnosticated as locomotor ataxia; kyphosis of the twelfth dorsal and three upper lumbar vertebræ; paresis of the lower extremity; unilateral sensory disturbances; Laminectomy second and third lumbar vertebræ; gelatinous-small-celled sarcoma, partial removal; recovery so long (two years.)

Quensel, *Neurologisches Centralblatt*, 1898, p. 482.—Man, forty-eight years old. Initial symptom, difficulty in urination and weakness of the legs; complete paraplegia and incontinence; sensibility lost for all qualities below a line drawn around the second lumbar vertebra, the ninth rib, and three fingers above the navel. The only parts below this line that have sensory perception are the genitals, and a saddle-form area on the posterolateral side of the hips; myostatic irritability of the lower extremities increased; a gibbus at the spinous process of the eighth dorsal vertebra, and local tenderness. Operation, removal of the spinous processes and arches, from the ninth to the fifth dorsal. A sarcoma the size of a pigeon's egg, situated on the dura posteriorly and latterly, was found between the seventh and eighth roots; it was apparently completely removed. The patient died of septic meningitis on the sixth day after operation.

Clark, J. M., *Brain*, Vol. 18, p. 256.—Man, twenty-eight years old. Initial symptoms, weakness of the arms and legs, dull pain in shoulders; later, paresis of the legs and arm, slight wasting of the small muscles of the hand; paraplegia, increased knee jerks, ankle clonus; loss of sensation in the arms and body. Two years later, operation, removal of the spine from the fifth cervical to the first dorsal. Spinal canal found to be completely filled with endothelioma of the dura. Death from shock. After hardening of the cord, the tumor was found to extend from the origin of the fifth cervical nerve roots to that of the first dorsal, chiefly on the posterior aspect of the cord, it lay external to the dura, 2¼ inches long, 1¾ inches in breadth, and 1¼ inches in thickness.

McCosh, *Journal of the American Medical Association*. September 7, 1901.—Male, thirty-nine years old. Initial symptoms, lancinating pain in posterior part of right thigh to the back of knee with great severity; treated for sciatica; pain, tenderness in the lower lumbar region; no paralysis, no anæsthesia; knee jerks normal; later numbness of the posterior and outer surface of the left thigh and foot; removal of spines of first and second lumbar vertebræ showed a sarcoma, which was removed; quick and satisfactory recovery. Probably all of tumor not removed, therefore recovery not permanent.

Case II.—Male, forty-six years old. Initial symptoms, pain on the outer side of ankle; later sacro region, inside of thigh worse on defecation, and when the bladder was full; loss of power of right leg and thigh; partial anæsthesia along the right posterior thigh and leg, and over the side of foot; on the buttock and externally to this there was a narrow line of hyperæsthesia. Both reflexes feeble. Operation, spine and laminæ, second, third, and fourth lumbar vertebræ removed, exposed dark-red purplish mass, completely hiding the dura; the tumor was irregular size, 2½ inches in length, spread out more than half-way around the cord; recovered.

Abbe, *Journal of Nervous and Mental Diseases*, 1902, p. 281.—Male, thirty-two years old. Initial symptoms, pain between the shoulders after a fatiguing game of golf; subsequently, numbness and spastic flection of the fingers, later of the legs and arms. Operation, three years after onset of the symptoms, which had been thought to indicate cervical hyperthropic pachymeningitis; removal of the laminæ from the fifth cervical to the third dorsal vertebræ. An intramedullary tumor attached to the anterior wall of the central canal, sarcomatous in nature, was found, and removed. The patient made a fair recovery, but has not gained much voluntary power.

Henschen and Lenander, *Upsala Läkareforenings Forhandlingar*, 1900-1901, p. 453.—Man, fifty years old. Removal of a tumor at the fifth dorsal vertebra. Before the operation the patient was completely paralyzed; recovery to such a degree as to enable the patient to get about. The destruction which the tumor had produced precluded complete recovery.

Alexandroff and Minor, *Neurologisches Centralblatt*, 1896, p. 1048.—Girl, twelve years old. Symptom complex of compression myelitis at the level of the fourth cervical segment, developing in three and a half months; resection of the arches of the fifth and sixth cervical vertebræ revealed thickening and protusion of the dura. The operation was carried no further. The patient died of pneumonia. Autopsy revealed an endothelioma attached to both the dura and the vertebra.

Starr, *Philadelphia Medical Journal*, 1902, p. 289, Vol. IX.—Woman, thirty-five years old. Initial symptoms, pain near the heart at night, occurring in paroxysms. Had been treated for angina pectoris; marked tenderness in the dorsal region, first to seventh dorsal spines; partial anæsthesia of trunk, total anæsthesia in the legs; motor paraplegia, double ankle clonus, loss of sphincter control. Operation and removal of a fibroma 1½ inches long, intradural, lying directly upon the cord and reducing its diameter about one-half at the level of the eighth cervical vertebra; death four weeks afterward from sepsis.

Case II, *Journal of Nervous and Mental Diseases*, 1902, p. 289.—Woman, forty-six years old. Initial symptoms, pain over the left hip, extending down to the left knee. Paralysis of the peronei and anterior tibial muscles; sphincter disturbances; anæsthesia back of the left leg and thigh; tenderness on pressure over the second, third, and fourth lumbar vertebræ. Operation, removal of the spines and arches of these vertebræ showed an endothelioma, involving both the soft and hard tissues of this region. Patient made a rapid and satisfactory recovery. The recovery could not be permanent because of the nature of the disease.

Oppenheim, *Berliner klinische Wochenschrift*, 1902, No. 2.—Man, forty-five years old. Initial symptoms, pain in the left hypochondrium and area innervated by the eighth to the ninth dorsal roots of two and one-half years' duration. It had been treated for rheumatism and intercostal neuralgia. Loss of abdominal reflex; atrophic paresis of the abdominal muscles on the left side; diminution of sensitiveness for touch and pain in the left hypochondrium; depreciation of temperature sense in the right thigh; later paraplegia; analgesia, especially in the right lower extremities; increased knee jerk, foot clonus, Babinski phenomenon, girdle pain. Operation at the sixth dorsal vertebra; on opening the dura, a myolipoma 3½ cm. long, and the thickness of a hazel nut; death eighteen days afterward from purulent cerebrospinal meningitis.

Case II, *Berliner klinische Wochenschrift*, 1902, p. 645.—A girl, eighteen years old. Initial symptom, pain in the right half of the abdomen. Scoliosis had been diagnosticated and orthopedic treatment advised; weakness and stiffness of the legs, especially the right; spastic paraparesis; foot clonus and Babinski phenomena on the right side; hyperæsthesia for tactile and pain stimuli; duration of the disease between six and eight months; relatively slight intensity of pain and failure of all root symptoms was taken to indicate primary medullary involvement; eighth dorsal vertebra point chosen for operation; tumor about 3 cm. long, fibroma, beneath the dura, attached to the arachnoid, readily removed; complete recovery in two months.

Putnam and Warren, *American Journal of the Medical Sciences*, October, 1899.—Woman, fifty-two years old. Initial symptom, intermittent severe pain over the lower ribs and left side across the abdomen into the left groin. Symptoms considered to be neuræsthenic or digestive. Six months later, weakness of the left leg, and bent over position, pain was then less excruciating; exaggeration of the knee-jerks and ankle clonus; sensibility to touch and pricking slightly impaired over the anterior surface of legs and lower part of abdomen; impairment of sensibility and motion increased until she was unable to stand alone, incontinence of urine; impairment of sensibility over the anterior and lateral surfaces of the thigh, legs, and feet, ceasing abruptly at the groin on both sides, but slight impairment was observable over the whole abdomen; sensibility of the left leg was better than that of the right, while the loss of motion there was much greater; to some extent, Brown-Sequard syndrome. The spines of the four lower dorsal vertebræ were removed, and a fibroma about the size and shape of an olive, lying in the meshes of the pia, on the left side, beneath the ninth dorsal vertebra, was removed; recovery.

Case II.—Man forty-three years old. Initial symptom, intense pain in the lumbar region, later impairment of sensation and motion of feet, with continuance of pain. At the end of nine years, entire paralysis of sensation, motion, and control of the bladder and the rectum; syringo-myelia-like disassociation of sensibility; operation, but no tumor found, second operation six years later, the same place, namely, seventh, eighth, and ninth dorsal vertebræ; some soft tissues found, which, on examination, proved to be endothelioma.

Case III.—A young man, twenty-four years old. Had difficulty in walking and use of hands; trifling disturbances of sensibility, exaggeration of knee-jerks and wrist-jerks; both legs and arms become wholly paralyzed. Operation revealed a sarcomatous mass in the upper part of the cervical cord, which was removed in part, and which gave relief, but, from the nature of the disease it could not be cured.

Eskridge and Rogers, *Philadelphia Medical Journal*, February, 1898.—Man, twenty-eight years old. Complained of pain in the back, radiating to the front. Six months later paræsthesia of the legs and gradual paraplegia; sphincter disturbance, fifth dorsal spine sensitive to pressure; knee-jerks exaggerated; skin reflexes sluggish or absent; tactile sensibility diminished or lost from the soles to the fourth intercostal spaces; perversion of temperature sensibility over same area; pain sensation greatly lessened from the soles to the umbilicus; deep sensibility lost. Operation, removal of fourth and fifth dorsal spines revealed the cord pushed to the left side of the canal from the tops of the fourth and fifth dorsal vertebræ by a sarcoma of the bone; death nine days after operation.

Eskridge and Rogers, *Philadelphia Medical Journal*, December 10, 1898.—Intradural fibroma, third to fourth dorsal vertebræ; removal and recovery.

CASES NOT SUBMITTED TO OPERATION.

Schultze, *Loc. cit.* Case III.—Man, thirty-six years old. Initial symptoms, numbness in the left leg, pain and stiffness in the neck; numbness, weakness, and severe pain in the right leg; later same symptoms in the arm and sphincter disturbances; spastic paresis of the lower extremities; exaggerated reflexes; tactile sensibility diminished from the neck downward; temperature, pain, and deep sensibility normal; prominence and tenderness of the upper cervical region; increase of the painful spasticity of the lower extremities and later of the upper extremities. "The patient lay like a stick of wood, with continuous severe pain in the arms, legs, and chest." Duration of the disease two years; autopsy, tumor the size of a walnut at the level of the atlas, between the dura and the bone, which closed the foraram magnum in its right half.

Case IV.—Man, twenty-eight years old. Initial symptoms, pain in the coccyx, numbness in the back and pain in the lower extremities; sphincter disturbances; paresis of the lower extremities; complete loss of the tendon-jerks; loss of tactile sensibility in the middle area, and on the right side of the anus, and the external genitals, and on the posterior surface of the thigh, beginning 6 cm. above the knee-joints, and reaching 17 cm. up over the gluteal fold; likewise on the outside of the feet on both sides; increase of all the symptoms; complete motor paralysis of the lower extremities. The entire posterior surfaces of the leg later show complete loss of sensibility; duration of disease, eight months. Autopsy, an intramedullary glioma, reaching from the conus terminalis to the lower part of the dorsal regions, posterior to the center of the canal.

Henneberg, *Archiv fur Psychiatrie und Nervenkrankheiten*, Vol. 33, p. 973.—Man, twenty-four years old. Initial symptom, developed after violent over-exertion, increasing weakness of the left arm and leg, pain in the left arm, difficulty of moving the head, priapism; later mystagmus, narrowing of the left palpebral fissure and pupil; left anhidrosis; paralysis of the left trapezius and levator scapuli muscles; weakness of the diaphragm; increase of the left tendon-jerks, loss of pain and temperature sensibility on the right side, sphincter disturbances; death six weeks after the first symptoms. Autopsy showed a medullary glioma, beginning in the sixth cervical segment and extending to the third cervical, involving principally the lateral columns of the cord.

Nonne, *Archiv fur Psychiatrie*, 1900, Vol. 33, p. 3[illegible].—Girl, sixteen years old. Developed paraplegia of the lower extremity in a subacute way; disturbances of the sphincters and loss of sensibility for all qualities in the [illegible], reaching as high as the mammary glands; weakness of the fingers, hands, elbows, and shoulders; disturbance of sensibility in the ulnar region, later complete; reflexes entirely lost; sensitive to pressure over sixth cervical vertebra; skin sensibility lost up to level of seventh [illegible]; later paresis of upper extremities and bulbar symptoms, choked discs. Autopsy, myelogenous tumor, reaching from the upper cervical cord to the tenth dorsal, intramedullary. The cord was uniformly affected.

Orlowsky, *Neurologisches Centralblatt*, 1898, p. [illegible].—Girl, fourteen years old. Initial symptoms, pain in the back and progressive weakness of the leg, which eventuated in paralysis, atrophy, with lost knee-jerks and anæsthesia of the lower extremities, reaching as high as the ninth dorsal spine behind, and two inches below the navel in front, complete, except over the posterior surface of the thigh and outer side of the legs; sphincter disturbances, later, anæsthesia of the ulnar region, both sides, and paresis of the arms; duration of disease, fourteen months. Autopsy, endothelioma, arising from the pia, which had destroyed the entire lower part of the spinal cord, and had its greatest development in the last two dorsal and first lumbar segments. At the level of the ninth spinal roots the neoplasm spread itself out in two directions. The principal part extending in the subdural space, in the form of a case or covering to the cord, compressing it, and here and there extending into it. In addition there was a gliosis in the posterior columns, with cavity formations.

Pribytkoff, *Neurologisches Centralblatt*, 1898, p. 563.—Man, forty-one years old, developed in the course of a year and a quarter the symptom complex of Klumpke's paralysis; disturbance of sensibility in the upper part of the thorax and the ulnar side of both upper extremities, with simultaneous left side oculopupilary symptoms. A few days before death paraplegia developed suddenly, flaccid in type, with loss of reflexes. Autopsy revealed sarcoma the size of an apple at the junction of the cervical and dorsal segments of the cord, which destroyed the head of the first rib and the bodies of the two first dorsal vertebræ producing compression myelitis.

Wersiloff, "Gesellschaft Neuropathologen und Irrenärzte zu Moskau in *Neurologisches Centralblatt*, 1898.—Age and sex not given. Duration of disease three and a half months. Sudden onset with spastic spinal paralysis of the left extremities, and loss of sensibility on the right half of the body and the right lower extremity. Later paralysis of the right extremity; increased tendon and cutaneous reflexes; no indications of compression of the posterior roots. Autopsy, angiosarcoma-psammoma, having its origin from the dura at the level of the second cervical roots, which compressed the cord on the left side to a severe degree.

Hudson, Barker and Flexner, *American Journal of the Medical Sciences*, Vol. 117, 1899, p. 648.—Man, fifty years old. Attributes symptoms to being thrown from a horse. Initial symptoms, pain along the spine from the dorsal region downward, and burning in the legs and feet. A year later, difficulty in walking; five years later, complete paraplegia, complete loss of sensibility in the legs, extending as high as the nipple line; violent spasmodic contraction of the muscles of the legs; skin reflexes present in the legs and feet; ankle clonus, exaggeration of the knee-jerks, no rigidity or deformity of the spine. Autopsy showed a peculiar glioma, extending from the fourth cervical to the dorsal region, which seemed to replace the cord particularly in the lateral parts, and extending above and below in two cone-like projections.

Fraenkel, A., *Deutsche medicinische Wochenschrift*, 1898, p. 442.—Male, thirty-three years old; shoemaker. Initial symptom, stabbing pain in the muscles of the throat, shoulders, and spine, later weakness of the back and arms; gait unsteady: patella-jerks slightly increased and indefinite sensory disturbances in the hands; later paralysis of the left upper extremity and inability to stand; difficulty in voiding urine, later complete paraplegia, and patellar reflexes lost; death six weeks after the initial symptoms. Autopsy showed a tumor in the upper part of the cervical region, reaching to the dorsal region, a gliosarcoma. The diagnosis of tumor had not been made during life. The tumor sprang from the pia, and there were metastatic deposits in other parts of the cord.

Case II.—Man, twenty-one years old. Initial symptoms, pain and tension in the right hip, which had been injured a year before; bladder symptoms; weakness of the legs, gradually increasing contraction of the lower extremities, pain in the neck; tendon reflexes not elicitable; plantar reflexes absent; complete anæsthesia of the lower extremities; no paræsthesia, no tenderness of the spine. Autopsy revealed, in the lower part of the dorsal cord, a soft grayish tumor mass, arising from the arachnoid, no connection with the dura; tumor began at the upper part of the lumbar enlargement, was 12 cm. long; it extended equally forward and backward, and made a pillow-like covering over the spinal cord. The tumor was a typical neuroepithelioma glioma cyst.

H. M. Fletcher, *Journal of the Pathological Society of London*, Vol. 49, p. 6, 1898.—Man, fifty-five years old. Initial symptoms, pain and weakness in the right knee; a year later similar complaint of left knee; difficulty in passing water, flaccid paraplegia, absent knee-jerks, sluggish plantar-jerks; impairment of sensation over both legs and trunk, as high as the upper edge of the sacrum, and the anterior superior spine; duration of disease, sixteen months. Autopsy showed a glioma sarcoma, 1½ inches long, in the lumbar enlargement, upper limit twelfth dorsal nerve root line, on the posterior surface of the cord, extending around on both sides, but not involving the interior surface. (This tumor should have been easily removed, although it could not have been accurately localized from the symptoms that are given. It is noteworthy that the patient died very suddenly with an attack of abdominal pain, attended by symptoms of collapse, which were thought to indicate that an abdominal aneurysm had ruptured into the retroperitoneum.)

Bonvenuti, Stratto del Vol. per il XXV anno dell'insegnamento chirurgico di Francesco Durante, Roma Societa, Editrice Dante Alighiere, 1898, Vol. 2, p. 375.—Woman, thirty-seven years old. Initial symptoms, pain in the lumbar region, radiating around like a girdle; paræsthesia and loss of strength of the lower extremities, especially of the left side, and exaggerated knee-jerk; abdominal and cremasteric reflexes diminished; slight general tactile anæsthesia; hyperæsthesia in the lower abdomen and loins; paralysis of bladder and rectum; later pain in the dorsal region, radiating to the upper extremities into the sides of the chest; loss of strength of arms, paresis of the muscles of the chest and anæsthesia of the thorax; breathing entirely diaphragmatic. Autopsical diagnosis, angiosarcoma of the pia, extending into cord.

Bailey, *Journal of Nervous and Mental Diseases*, 1896, p. 171.—Woman, sixty-five years old. Initial symptoms, chill, headache, vomiting, symptoms of pneumonia; death in sixteen days. Autopsy revealed on the dorso-internal surface of the dura, between the seventh and eighth dorsal nerve roots, a tumor of the size of an almond, and of the nature of a psammoma. The tumor, which was adherent to the dura, was directly opposite the posterior longitudinal fissure, and its long axis corresponded to that of the canal. It had never caused symptoms.

Case II.—Woman, twenty-nine years old. Initial symptom, paralysis and numbness of all four extremities, which disappeared after ten months. Four years later, similar attack, and disturbance of the sphincters; partial recovery. A year later, recurrence; extensor paralysis with contraction of the flexors of all four extremities; tendon-jerks lively; sensation normal, save for blunting of tactile sensibility in the fingers; muscular sense unimpaired; no tenderness over vertebral spines; no pain. Autopsy revealed a tumor of the ventral portion of the cord, on the external surface of the dura, slightly adherent to the loose fat on the spinal canal. It encroached upon the right first, second, third, and fourth cervical nerve roots, and on the first, second, and third on the left side.

Collins, *Medical News*, July 10, 1897.—A man, thirty-six years old. Initial symptoms, pain in the back of the neck, radiating to the front, and to the right side of the face; spasticity of the neck, partial loss of strength in the left side; all the tendon-jerks exaggerated in this side; left side hemiplegia. Autopsy revealed a tumor, gliosarcoma, of the pia, at the first cervical segment. Mistaken for hypertrophic pachymeningitis.

Raymond et Nageotte, *Journal de Neurologie et d'hypnologie de Bruxelles*, 1896, Nos. 1 et 2.—Man, twenty-six years old. Initial symptoms, pain and weakness in the leg and pain in the seventh left intercostal space, paraplegia, at first spasmodic, afterward flaccid, then pain disappeared; complete anæsthesia as far as the eighth dorsal vertebra, and sphincter incompetency; duration of disease, four months. Autopsy, a trilobed tumor, situated at the sixth intervertebral space, sending out three prolongations, one toward the body of the fifth dorsal vertebra, the other into the pleural cavity, between the sixth and the seventh spaces, and the third into the spinal canal, compressing the posterior surface of the cord at the emergence of the seventh and eighth dorsal roots.

Case II.—Man, forty-nine years old. Initial symptoms, progressive enfeeblement of and pains in the lower extremities; spasmodic paraplegia; various sensory troubles in the lower extremities, irregularly distributed, corresponding to no definite area of supply; pains radiating into the arms, and attacks of pseudoangina. Autopsy showed a tumor about the size of a nut, between the eighth and ninth dorsal segments, compressing the eleventh dorsal nerve. The tumor was a sarcoma.

Sailer, "Proceedings of the Pathological Society of Philadelphia," New Series, Vol. 2, 1898–1899.—Man, thirty-four years old. Initial symptoms, sharp stabbing pain in feet and legs, and unsteady gait; tenderness over nerve trunks; absent knee-jerks; sensation normal. Autopsy showed a tumor, melanotic sarcoma of the cauda equina, lying to the left of the lumbar enlargement of the spinal cord, and extending downward to the level of the conus terminalis. Tumor surrounded by fibrous envelope, which prevented it from invading the cord.

Cladek, *New York Medical Journal*, August 14, 1897.—Man, fifty-one years old. Initial symptom, pain in the right side, between ribs and ilium shooting into pains and testicle; six months later, paralysis of lower extremities, bladder, and rectum, sensibility dulled, but gradually got worse. Partial autopsy showed a growth springing from dura, extending from second lumbar to ninth dorsal. segments (Incompletely reported.)

Marfan, *Semaine Médicale*, Vol. 17, p. 29.—Child, three years old. Initial symptom, incomplete spastic paraplegia, incontinence of urine and fæces, and slight trophic troubles; no sensory disturbances, amelioration. Some months later, opisthotonus, general convulsions; death. Autopsy, solitary tubercle of the sacral cord; hæmatomyelia of the zone immediately subjacent, subarachnoid hemorrhages, hemorrhagic ascending poliomyelitis, and intense diffuse phlebitis of the veins of the pia.

Rosenthal, Ziegler's "Beitrage zur Pathologischen Anatomie;" Vol. 23, 1898, p. 111.—Man, twenty-five years old. Pain in back, loin, and abdomen, then difficulty in urinating and defecating, unsteadiness of gait, "cramps" in legs, paraplegia, sensibility of right leg diminished, profoundly so of the left, abdominal anæsthesia, skin and tendon-jerks exaggerated; gradual increase of symptoms; duration of disease, five years. Autopsy showed peculiar tumor of cord, associated with syringomyelia. Neuro-epithelioma, mycrocystic glioma, ninth to tenth thoracic vertebra 45 cm. long, 11 cm. wide.

Potts, "Proceedings Pathological Society, Philadelphia," January 15, 1898, Vol. 1, 1897–1898, p. 20.—Boy, sixteen years old. Leg amputated eighteen months before for sarcoma of knee. Initial symptoms, weakness of the right leg, numbness, and tingling. In two weeks complete paralysis of the leg, no pain; knee-jerks increased, ankle clonus, skin reflexes sluggish or absent; anæsthesia, extending up to the umbilicus; duration of disease, five months. Autopsy, sarcoma of dura from the ninth to the eleventh rib, anterior to cord (location probably explains absence of pains).

Morton and Witmer, "Proceedings of the Pathological Society, Vol. 1, 1897–1898, p. 1.—Woman, thirty-one years old. growth, metastatic from breast. Autopsy: tumor adherent to dura, twelfth thoracic vertebra; sarcoma size 33 cm. by 25 cm. by 19 cm.

Moeller, *Deutsche medicinische Wochenschrift*, Vol. 23, 1897.—Man, fifty-three years old. Initial symptom, tremor, then pain in legs; difficulty of urination, difficulty in locomotion; flaccid paralysis of lower extremities; complete anæsthesia below a line drawn around the navel to the second lumbar vertebra. Tendon-jerks of the lower extremities not much altered; duration of disease, two months. In the spinal cord between the eleventh and twelfth dorsal vertebræ a gliosarcoma, replacing nearly the entire right half of the cord. (Metastatic in lungs, stomach, and suprarenals, which is uncommon.)

Raymond and Cestan, *Revue Neurologique*, February, 1902, p. 174.—Male, thirty-two years old. Initial symptom, heaviness of the left leg, which soon progressed to a spasmodic paraplegia, extensor type; progressive evolution; appearance of anæsthesia superimposed upon the motor troubles; sphincter disturbance; painless bed-sores over the sacrum; death, six years afterward. Autopsy, psammoma, angiolithic sarcoma, endothelioma, adherent to the anterior of the dura, and compressing the sixth, seventh, and eighth dorsal roots.

Fischer, *Zeitschrift fur Heilkunde*, Vol. 22.—Girl, three years old. Initial symptoms, pain in the loins and weakness in the legs; complete flaccid paraplegia; disturbance of the bladder; loss of sensibility for all qualities in the lower extremities and the trunk, from the fourth to the fifth ribs, downward on the right side, from the sixth to the seventh on the left, and from the ninth dorsal vertebræ; spinal column not sensitive; weakness of the upper extremities, later paralysis; choked discs. Autopsy, an enormous gliosarcoma, not only of the cord itself, but of the coverings, soft and hard, and deposits in different levels of the cord.

Holmsen, *Norsk Magazin für Lægevidenskaben*, 1901, p. 318.—Boy, eight years old. Initial symptoms, pain in the loins and abdomen, paresis of the left leg, ataxia of both, spastic ataxic gait, increased reflexes; paraplegia, incontinence of bowels and bladder; loss of sensibility from the ensiform process downward; pain and paresis of left arm, stiffness of neck, headache, vomiting, epileptiform attacks. Autopsy, sarcoma, between the dura mater and cord, throughout its entire length, thickest in the upper dorsal and lower cervical, compressing the cord most at the seventh and eighth dorsal segments.

Schlagenhaufer, "Arbeiten aus Obersteiners' Latoratorium," Vol. 8, 1902.—Woman, sixty-one years old. Initial symptom, weakness and œdema of the right arm; later, paralysis of all the extremities, the bladder, and the bowels, anæsthesia of the extremities and the trunk; patellar reflexes lost. Autopsy, circumscribed tumor, psammoma endothelioma, at the foramen magnum, springing from the dura, compressing and almost obliterating the first dorsal segment.

Sibelius, *Finska Lækaresellskapets Handlingar*, 1890, No. 9, p. 1021.—Man, twenty-five years old, in whom sarcoma developed in the spinal cord, and pursued its course without pain. The writer thinks that the tumor because of its way of progression, provoked a lymph stasis, which rendered the nervous elements incapable of performing their function, and for this reason the tumor did not cause any pain.

Roux and Paviot, *Archives de Neurologie*, Vol. 5, 1898.—Man, forty-five years old. Initial symptom, pain in the left arm, the dorsal lumbar [illegible] then the lower extremities, spasmodic paraplegia, later complete loss of cutaneous sensibility, with the preservation of [illegible] in the lower extremity and sphincter disturbances, painful spasmodic contractions of the muscles of the lower limbs, evidences of root compression. Autopsy, a [illegible], in the left lateral half of the cord reaching from the sixth cervical to the second dorsal segment.

Touche, *Revue Neurologique*, Vol. 8, 1900, p. [illegible].—Age and sex not given. Clinical history, spasmodic paraplegia with incontinence of the sphincters, exaggerated patellar reflexes, phenomena of Brown-Sequard, sensibility was first abolished, later it became normal in all [illegible]. Autopsy, tumor the size of a pigeon's egg beginning at the upper border of the lumbar enlargement, extending upward 3 cm., occupying the posterior surface of the cord without being adherent to it, and reducing the cord at this level to the thickness of a ribbon. The remarkable feature in this case is the preservation of sensibility, though all the white matter of the cord was destroyed at the level of compression.

Case II.—Age and sex not given. Initial symptom, unbearable pain in the left lower extremity, shooting from the trunk to the foot, then going into the other extremities extending from the foot to the body. Much later paraplegia with loss of the patellar reflexes, fixation of the knees in extension, and of the feet in equino varus, incontinence of the sphincters, integrity of tactile and pain sensibility in the posterior part of the dural surface, and malleolar region of the right foot, abolished elsewhere. Autopsy, a tumor the size of a nut in the mid-dorsal region, on the posterior surface of the cord, absolutely independent of it, but making unequal compression upon its two halves. It compressed completely the left half, reducing it to the thickness of a ribbon, and exercised equal compression on the left sixth dorsal nerve. On the right half the compression was much less. Nature of tumor, angiolithic sarcoma.

Muller, *Deutsche Archiv für klinische Medicin.*—Man, forty-six years old. Initial symptoms, headache, pains in the legs, and disturbance of urination. Patient was deranged mentally; inability to stand or walk because of severe vertigo; double choked discs, hyperæsthesia of the lower part of the body and legs, no anæsthesia; gradual paraplegia, first of the right, then of the left leg, with complete incontinence and trophic manifestations. Autopsy showed sarcoma of the left kidney, with metastatic deposits in other organs of the body, including the brain and spinal cord. The tumor of the cord was situated between the second and third thoracic nerves on the posterior surface, covering about one-fourth of the periphery and springing from the arachnoid.

Schlesinger, *Wiener klinische Wochenschrift*, 1897, No. 47.—Woman, sixty-one years old. Initial symptom, pain in the loins, and stiffness of the spinal column; later, paralysis of the detrusor and sphincter vesica, and anæsthesia of the bladder; later, incontinence of stools, and anæsthesia of the anus, perineum and external genitals. Autopsy, carcinoma of the first lumbar and twelfth dorsal vertebræ, which extended into the spinal canal, compressing the cord as far upward as the fourth cervical segment.

Saenger, *Munchener medicinische Wochenschrift*, 1898, Vol. 45, p. 978.—Woman, thirty years old. Initial symptom, weakness of the right leg, and slight pain in the back of the knee; later, numb feeling of the right foot, difficulty in standing and walking, functions of bowels and bladder somewhat disturbed; loss of patellar and achilles reflexes; disturbance of sensibility in the left lateral cutaneous, crural, and superficial peroneal nerves. Until a week before her death, patient was able to get about in a room with a stick; death, very suddenly, as if from a heart stroke. Autopsy showed intramedullary glioma, reaching from the lower dorsal segments to the conus medullaris, extending throughout the cord, swelling it to about twice the normal size. In the dorsal cord, a second tumor the size of a hazel nut.

Mader, *Wiener medizinische Blätter*, No. 10, 1898, p. 240.—Male, twenty years old. Initial symptoms, weakness of the legs, and pain in the toes on movement, later pain in back, sphincter disturbances, flaccid paraplegia, weak tendon-jerks, sensitiveness to pressure at the lower dorsal vertebra, no objective sensory disturbances; death six weeks after first symptom. Autopsy sarcoma (endothelioma of the dura in the lower part of the dorsal cord).

Strube, "Charité Annalen," Vol. 23, 1896–1897, p. 27[illegible].—Man, fifty-eight years. Initial symptoms, paralysis of both legs within two weeks, complete paralysis of the lower half of the body with bladder and rectum disturbances; complete loss of sensibility from the navel downward, trophic disturbances, in the form of œdema and decubitus; duration of disease, two months. Autopsy showed cystic myxosarcoma of the dura mater, the size of a hazel nut, between the sixth and eighth thoracic segments.

Wyss, *Correspondenz-Blatt fur Schweitzer Aerzte*, Vol. 29, 1899, p. 110.—Girl, twelve years old. Initial symptom, gradual increasing paraplegia; insensibility of the lower extremity; sphincter disturbances, first considered to be hysterical; left tendon reflexes absent; right, weak; later progressive weakness of the upper extremity; dyspnœa. Sensory disturbances not carefully observed. Autopsy showed medullary glioma with extension throughout the cord.

J. J. Thomas, *Journal of Nervous and Mental Diseases*, 1900, p. 580.—Woman, twenty-two years old. Initial symptom, gradual loss of power in the leg, later spasmodic, sudden contractions, paraplegia at the end of ten months; sensibility in all forms lost from the mid-dorsal region downward; function of the vesical and rectal sphincters abolished; duration of disease, thirteen years. Autopsy: just below the cervical enlargement, and at the level of the spine of the scapula, an endothelioma about 2.5 cm. in length, which appears to be meningeal, but which almost completely replaced the cord beneath it.

Case II.—A boy, six years old. Initial symptoms, weakness of the right hand and arm, pain in the shoulder, and rotation of the head to the left, from muscular spasm; later paralysis of the arm, and, to a lesser degree, of the leg, on the right side, with increased tendon reflexes; death very sudden at the end of the fifth week. Autopsy, glioma of the entire cervical enlargement of the cord.

E. Meyer, *Deutsche Zeitschrift für Nervenheilkunde*, Vol. 22, p. 232.—A girl, fourteen years old. Initial symptom, pain in the left shoulder and arm of great severity; numbness and weakness of the left arm; one and a quarter years later, stiffness and weakness of the left leg, associated with numbness, no pain; three months later, gradual stiffness and weakness of the right side; shooting pains in both arms, radiating from the neck, fifth vertebra; loss of sensibility for all kinds of stimuli in the inner half of the right upper extremity, anterior, and posterior surfaces, extending on the chest as far forward as the nipple, as low as the seventh rib, and behind to the middle of the scapula; complete anæsthesia over the left ulnar distribution; later, diminution of sensibility, and both lower extremities, extending up on the anterior surface to the epigastric region; tenderness of the fifth cervical; duration of disease, two years and eight months. Autopsy showed a fibrosarcoma, reaching from the sixth cervical to the first dorsal segment; it was divided into two portions, each about the size of a walnut, one extradural, the other intradural, the two connected by a bridge.

ARE VESSELS INFECTED WITH YELLOW FEVER?

A REPLY TO DR. CARTER.

By ALVAH H. DOTY, M.D.,

HEALTH OFFICER OF THE PORT OF NEW YORK.

In the Medical Record of March 22, 1902, appears an article, written by Dr. Henry R. Carter, Surgeon, Marine Hospital Service, entitled, "Are Vessels Infected with Yellow Fever? Some Personal Observations." This is also published in the *Yellow Fever Institute Bulletin* of the Marine Hospital Service (July, 1902). From the text of the article, I assume that it is intended as a criticism of, and a reply to, my paper, which was read at the meeting of the American Public Health Association, held in Buffalo in October last.* "On the Mode of Transmission of the Infectious Agent of Yellow Fever and Its Bearing upon Quarantine Regulations." The first paragraph of Dr. Carter's article contains the following: "Dr. Doty, the quarantine officer of New York, affirms the absence of secondary cases of yellow fever aboard vessels; *i. e.* that, while cases of this disease contracted ashore develop aboard vessels, yet none are contracted on board the vessel itself; that is, the vessel does not become 'infected' with yellow fever." Dr. Carter has unintentionally misquoted me. In the paper to which he refers, I did not make the statement that yellow fever is never transmitted on shipboard by mosquitos. What I said regarding this part of the subject is as follows: "It is not impossible for this to take place, and instances have been reported where secondary cases have occurred after leaving port. How many of these statements are authentic, I do not know, but of this I am quite sure, that it occurs only in rare instances." I am satisfied that the mosquito is the principal, if not the only, medium of infection in yellow fever; therefore, it would hardly be scientific or logical to claim that this disease cannot be transmitted on shipboard; however, I believe this to be uncommon, and have presented my personal experience at the New York Quarantine in proof of it. This, I am quite sure, is entitled to consideration, inasmuch as the port of New York receives about one-half of all vessels coming to the United States from foreign ports, and vessels from Rio Janeiro and other yellow-fever-infected ports are daily arriving at this station. Dr. Carter evidently believes that secondary cases of yellow fever on shipboard are of frequent occurrence; this practically constitutes the difference of opinion between us. It is true that Dr. Carter and I present evidence from two different periods. He refers to a time when sailing vessels, which usually remain many days in port, were more commonly employed in the Southern trade. In recent years these have been largely replaced by steamships; besides, better sanitary regulations now exist at the ports of departure. To a certain extent this may account for the difference in our conclusions. However, I cannot admit that this is the principal factor. In the consideration of this subject, it is very necessary that we should bear in mind that the discovery of the malarial plasmodium by Laveran has thrown great light on the differential diagnosis of malarial and yellow fever, and I am quite sure that Dr. Carter will agree with me that the diagnosis of the latter disease is at times very difficult, and that even our most skilful diagnosticians in the South and elsewhere have frequently been unable to agree as to the diagnosis of certain cases alleged to be yellow fever. This, undoubtedly, has been largely due to the fact that some forms of malarial fever and yellow fever bear a close resemblance to each other. In obscure cases careful and conservative quarantine officials give the public the benefit of the doubt. This has oftentimes forced an official diagnosis of yellow fever in order that detention, disinfection, etc., may be carried out.

In support of his claim that secondary cases of yellow fever frequently occur on shipboard and under the heading of "personal observation," Dr. Carter refers to thirteen vessels on which it is alleged secondary cases of yellow fever occurred. On seven of these vessels, viz., *Magnolia*, *Riagino*, *Queen of the Seas*, *Curlew* (1901), *Condoran*, *Gustav and Oscar*, and *Crown Prince*, the members of the crews said to have had yellow fever were not seen by Dr. Carter, as they were sick at sea and died or recovered many days before the vessels reached the United States. There is no evidence presented to show that an autopsy was made; that a surgeon was in attendance on board these vessels, or that the sick received any intelligent medical aid. Therefore Dr. Carter's information as to the character of the disease must have been obtained from an inspection of the ship's log, or from the statement of the captain, or a member of the crew. So far as I am able to classify the statistics presented by Dr. Carter, it appears that there were, in all, 113 cases of sickness; of these 102 were on the seven vessels above named, and were not seen by Dr.

---

*Medical Record, October 26, 1901.

Carter: therefore, out of the entire number but eleven were under his personal observation.

Dr. Carter refers to a case of yellow fever which occurred on the British ship *Avon*, and which came directly under his observation at Quarantine. The patient, a boy, became sick with the disease thirty-eight days after leaving Rio Janeiro, and was ill on arrival at the Quarantine Station, and died three days afterward. Dr. Carter states that it was suggested that the disease may have been contracted by the escape of an infected mosquito from a box packed at the port of embarkation, and which was overhauled by the boy at least a month afterward. I am satisfied that the infection was not transmitted in this manner. In a series of experiments carefully made at this Station during the past year, it was conclusively shown that mosquitos thus confined do not live more than four days. These experiments were made as follows: Boxes and bags, similar to those used in the forecastle of a ship, were filled or partly filled with clothing, blankets, etc. In each receptacle were placed ten or fifteen mosquitos. These insects, which had been caught in cages, were not handled, but were allowed to escape into the bags and boxes containing the material referred to; great care being taken not to injure them by pressure. In order to avoid this some of the mosquitos were transferred to the boxes and bags and among the folds of the clothing in large open test tubes. These precautions gave better protection to the insect than when they are accidentally imprisoned at the port of departure. In these tests the mosquitos were, as a rule, found dead at the end of forty-eight hours. In no instance did they survive the fourth day.

In referring to the British ship *Curlew*, fifty-seven days from Rio Janeiro for Pensacola, Dr. Carter states that, with the exception of a Barbados negro, the crew were all sick, and some had black vomit. He adds that he does not believe that all had yellow fever. Inasmuch as the Doctor was not on board the *Curlew*, and saw none of the cases, and as no professional statement was in evidence, on what grounds is he willing to declare the existence of secondary cases of yellow fever on this vessel? Those of us who are constantly dealing with the type of vessels referred to by Dr. Carter know that the statements made by sailors cannot always be relied upon. Furthermore, those who sail to Southern ports are usually familiar with the term "black vomit," and in a way appreciate its significance, and often apply it to matter evacuated by the stomach in other diseases than yellow fever.

In conclusion, Dr. Carter states: "I think it will be granted, from the above, that the ability of a vessel to carry the infection of yellow fever is no myth. Here are thirteen vessels which did carry it, collected from only three years' observation at a single station." It is unnecessary for Dr. Carter to present evidence to show that it is possible for secondary cases of yellow fever to occur on shipboard. We all agree that this may take place, but I am quite sure that it will require more conclusive evidence than Dr. Carter has presented to prove that secondary cases of yellow fever on shipboard are of common occurrence. No practical sanitarian has given the subject of yellow fever more careful and diligent study than Dr. Carter, and his efforts to bring about a solution of the problem now before us have been exhaustive as we all know. If the cases on the vessels referred to by Dr. Carter had been under his personal observation, and he had made a positive diagnosis of yellow fever, there would be nothing in his article to criticize. We cannot, however, accept as conclusive evidence the diagnosis of yellow fever made by laymen particularly when we know that this disease is often closely simulated by malarial fever.

A NEW STAIN FOR DIPHTHERIA BACILLI.

By WILLIAM GRAY SCHAUFFLER, M.D.
LAKEWOOD, N. J.

During July and August, 1902, it was my privilege to work in the bacteriological laboratory of Dr. Max Piorkowski in Berlin, Germany. In the course of my work, I became especially interested in a method, perfected by Dr. Piorkowski, for demonstrating quickly and surely the presence in the bacilli of true diphtheria, of characteristic metachromatic bodies, called by the Germans "Polkörner."

In the *Berliner klinische Wochenschrift*, No. 9, 1901, Piorkowski published his method, with a careful résumé of the work done up to that date by other investigators. He has continued the use of the method up to the present time, and his results, as to ease of technique and accuracy of diagnosis, go far ahead of the pioneers in this work. M. Neisser[1], Ernst[2], A. Neisser[3], Babes[4], Delafield[5], Croush[6], Roux and Yersin[7], Gossage[8], Bronstein[9], Zupnik[10], Sahli[11], and Concetti[12], had used various combinations of stains, but claimed results only within certain limits of culture-media and time. Piorkowski, working with Pewsner of Riga, laid down the following rules: Use as culture medium preferably Löffler's blood serum. Keep the culture at 35 °C, and examine from ten to twenty-four hours after inoculating.

1. Prepare cover-glass smear.
2. Stain with Löffler's methylene blue, slightly warmed, one to two minutes.
3. Decolorize very rapidly (one second) with 3 per cent. HCl-alcohol.
4. Rinse in water.
5. Counterstain with ½ per cent. aqueous solution of eosin, ten seconds.
6. Examine in Canada balsam, or with clearer results in water.

This method stains the bodies of the bacilli a pale reddish color, while at each pole, and sometimes in the middle of the bodies, appear the dark blue-black polar bodies.

In searching for some color that would give more decided results, I tried pyronin (Grübler), and found it far superior to eosin. In order to simplify the method still further, I experimented until I hit upon a combination of colors which required the use of but one solution for one minute and cold, with much better results than anything previously attained. I also found that cultures on plain agar-agar, kept at 37° C., showed the characteristic staining after from seventeen hours to twenty-one days. Further than this time limit I did not carry my experiments. The clearest results were obtained after from twenty-four hours to five days. Of even greater importance was the fact that smears made from fresh diphtheritic membranes showed the characteristic staining, although not so clearly as in the cultures.

A mixed culture of true diphtheria bacilli and pseudodiphtheria bacilli stained in the same way, showed the characteristic pole-stained bacilli of true diphtheria, side by side with the much smaller pseudodiphtheria bacilli, the latter of uniform color throughout.

The practical usefulness of this method is that it furnishes a rapid and reliable means of recognizing the true diphtheria bacillus from fresh membranes as well as from cultures.

The solutions used for making the stain are as follows:

Filtered solution Löffler's methylene blue . . 10.0 c.c.
Filtered solution pyronin (Grübler) . . . . 1.5 c.c.

$$\left\{\begin{matrix}\text{Pyronin, 0.5 gram.}\\ \text{Aquæ dest. 10.0 c.c.}\end{matrix}\right\}$$

Three per cent. HCl-alcohol . . . . 0.5 c.c.

$$\left\{\begin{matrix}\text{Alcohol absol. 97.0 c.c.}\\ \text{HCl.(25 per cent.) 3.0 c.c.}\end{matrix}\right\}$$

To prepare specimen: (1) Make cover-glass smear, and fix by passing through a flame three or four times (2) Drop on to a fixed smear enough solution to cover it and let it stand one minute. (3) Wash thoroughly in running water. Mount in Canada balsam and examine with $\frac{1}{12}$ oil emersion lens. Magnify 1,000 times.

The above procedure will show the bodies of the bacilli stained blue while the poles are a bright ruby red.

As stated above, the pseudodiphtheria bacilli are much smaller and take on only the blue color. The bacilli of Asiatic cholera and of plague, when stained by this method, show granular bodies in their interior, but these bodies are not metachromatic like those of diphtheria bacilli just described.

Perforation of the Bowel in Typhoid Fever.—The paper of G. E. Armstrong of Montreal is of interest especially from its statistics of operations done in the author's own city. In this series the operation was performed during the first twelve hours in ten cases, with four recoveries, or 40 per cent.; the second twelve hours in ten cases, with one recovery, or 10 per cent. Of the twenty cases operated upon during the first twenty-four hours, five recovered, or 25 per cent. Operation was done during the third twelve hours on three patients, and they all died; on one patient, forty-eight hours after perforation, another sixty-eight hours after perforation, who also died; on one, seven days after perforation, who recovered; in seven cases, time after perforation uncertain. Of the six who recovered, one was operated on two hours after the perforation, one thirteen hours after, one eight hours, one ten hours, one five hours, and one seven days after. The operation in the last case was really nothing more than the opening of an intra-abdominal abscess. Four of the five acute cases were operated on during the first twelve hours.—*Annals of Surgery.*

Paradoxical Pseudohypertrophy Following Infantile Cerebral Hemiplegia.—L. Pierce Clark says that the hypertrophy of paralyzed parts in infantile cerebral palsy is a rare condition, no cases illustrative of it having, until now, been reported in America. In those reported in other countries the more important symptoms of the onset of cerebral palsy have usually been absent in the hypertrophic cases, but in those observed by the author there were more or less severe convulsions, vomiting, fever, and physical prostration. Athetosis may or may not occur. The mental state of these patients, on the whole, is better than usually obtains in palsy cases. The length of time necessary to produce the hypertrophy is difficult to ascertain, but the time elapsing between the palsy lesion and the detection of the hypertrophy has varied from eight to twenty-nine years, the average being sixteen years. The hypertrophy may involve any and all parts that are paralyzed, even the breast and the testicles may enlarge. The muscles most frequently hypertrophied are found in the following order of sequence: biceps, deltoid, and triceps. The parts not hypertrophic follow the general law for atrophies in ordinary cerebral palsy cases.—*The Journal of Nervous and Mental Disease.*

A Case of Trypanosoma in a European.—The wife of a missionary in the upper Congo, where she had lived for about a year, was sent to Dr. Manson in London. She complained of persistent fever and impaired health, with no improvement from the taking of quinine and arsenic. The group of symptoms found consisted of fever, enlargement of the spleen, not very marked, but distinct œdema of the face, and a multiform erythema. Examinations of the blood were made regularly for a fortnight, without result, but later, while the leucocytes were being counted, an unquestionable trypanosoma was found. On the examination being repeated, other specimens of the parasite were readily discovered. For some unknown reason the parasites must have been latent during the first part of the patient's residence in the hospital, or so very scanty in the peripheral circulation that they were overlooked. Possibly in the presence of this parasite we have an explanation of some of the anomalous chronic fevers, such as kala-azar, which have hitherto defied investigation in tropical countries.—*The Journal of Tropical Medicine.*

Giantism.—Henry Meige states that a comparative study of giantism shows that it is intimately related to acromegaly. There is an abnormal and excessive osteogenetic function which results in giantism so long as the bone is capable of increasing in length, and in acromegaly when ankylosis of the epiphyses interferes with the manifestation of the hypertrophy, except at the extremities of the bones. The cause of this perturbed function cannot as yet be definitely stated. But it is well to bear in mind the affinities existing between the bony development, the genital development, and the condition of the vascular glands, the thyroid in particular. Both giantism and acromegaly are frequently accompanied by general phenomena, such as pain, circulatory troubles, urinary and sexual disturbances. Giants belong to two types—the infantile and the acromegalic, with intermediate types. Marriage should be discouraged in individuals of either type.—*Archives Générales de Médecine.*

The Radical Treatment of Hernia in Arabia.—Dr. H. R. L. Worrall writes: "I think it may be of interest to know that some of the native surgeons here in Arabia treat inguinal hernia by reducing the hernia, then picking up the skin over the external opening, pass a needle through, including, if possible, the edges of the external opening in the muscular wall (on the opposite sides of the opening), and thus trying to make a closed way. One such case came to me to be treated for a return of the hernia. The cure lasted, he claimed, about two years and a half, the suppuration apparently helping the operation. The severe work which the patient had to do would cause a return of the trouble in almost any case. The work, although not the same, would correspond to longshoreman's work in America. As aseptic methods are absolutely unknown here, the remark that the suppuration apparently helped the operation is sufficiently explained."

PURE MILK LAW FOR THE DISTRICT OF COLUMBIA.

CONSIDERING the importance to large cities of purity in their milk supply, and the difficulties in the way of securing such purity, the important monographic résumé upon the subject of sanitary milk submitted by Dr. George M. Kober, Chairman of the Public Health Committee of the Medical Society of the District of Columbia, constituting Senate Document No. 441, in support of the bill pending before Congress to regulate the production and sale of milk in the District of Columbia, is a tract for the times. Dr. Kober's paper contains 235 pages, with a comprehensive bibliography, a thorough index, and the tabulated data of 330 epidemics of typhoid, scarlatina, and diphtheria, due to infected milk. Being in the nature of an argument designed for the Senate Committee, much of the paper is, of course, devoted to technical details, the chemical and bacteriological examination of milk for impurities and adulterants, and the proper methods of sanitary dairying. But a few points have a wider interest Thus, in appendix F, is described the relation of the milk supply to infant mortality. The mean death rate during the first year of life per 1,000, taking cities and country alike, is 188; that for the cities, as a class, 336, and that for the country, 278. The same rate is for:

Italy	273
France	223
England	142

Chemnitz	480
Paris	290
New York	277
Brooklyn	276
Boston	261
Washington	256
Liverpool	259
Philadelphia	230

The influence of hygiene upon the mortality is indicated by the fact that the rate for royal children is but 57 per 1,000, as compared with 345 among the poor. Moreover, the average mortality for France, Austria, Sweden, and England, for legitimate children, is 162, as against 312 for illegitimate. In Berlin, among hand and bottle-fed children, it ranges from 400 to 470; in Hamburg it is 294; while in Paris it has reached as high as 700 to 750. In Munich, of 8,329 children dying at six months or earlier, over 85 per cent. were bottle-fed. Of deaths during the first year, 40 per cent. occur from diseases of the digestive organs, and 2.5 per 1.000 die from primary tuberculosis of the abdominal lymphatics Again, during the first twelve months the mortality is heaviest the first month, then follows in order the second, third, and fourth months and then the twelfth month, the rise in the last month being attributed to the beginning of artificial feeding. Sour milk, or milk on the point of turning, is very liable to produce gastric and intestinal catarrhs, acute or chronic, in infants, children, and feeble individuals, and in bottle-fed children we may have the phenomenon of cholera infantum The causes of untimely acidity of the milk are improper feeding of the animals, dirty milk pans and rooms, unclean udders and teats, and a high temperature The greatest danger under such conditions lies in the possible production of tyrotoxicon and other bacterial products. The presence of excrementitious matter, containing a large number of fecal bacteria, on the udders and teats, and the pernicious habit of placing the milk before cooling in covered and, perhaps, dirty vessels, constitute conditions favorable for the production of bacterial toxins. The amount of filth in milk (largely bovine fecal matter) has been found by Renk to be, at Leipzig, 3.8 milligrams per liter; at Munich 9 mgms.; at Berlin, 10.3 mgms.; and at Halle, 12.2 mgms. In Washington, twenty-four samples of market milk taken at random, showed all the way from 5 to 30 mgms. per pint and quart. These sediments contained epithelial debris, hairs of the cow, excrementitious matter, vegetable fibers, organic and inorganic dust particles, bacteria, fungi, and spores of every description. Of the germs, 90 per cent. were those of fecal bacilli. The number of microorganisms per cubic centimeter in market milk in Washington being about 52,000, it was found possible, by sanitary dairying, to reduce them to 6,485 per cubic centimeter. Dr. Plant of Leipzig finds that the "fresh" milk delivered in the morning has already passed the period of incubation, and is unfit for young children. Of forty-seven infants whose milk supply he investigated, eighteen developed, under such conditions, digestive disturbances and six died. A number of cases of milk and cheese poisoning are given, the usual symptoms being vomiting, purging, abdominal pains and cramps, cold, moist skin, feeble pulse, etc.

Apart from wilful adulteration and dirty sediments due to uncleanly methods, milk may be unfitted for use through improper feeding of, or during the administration of substances by way of medicines to the cow. But an even more important matter is the unfitness which ensues upon diseased conditions of the animal. These are discussed at some length. Thus epidemics of so-called diphtheria and scarlatina have been caused by the milk of cows suffering from inflammatory diseases of the udder, or from puerperal fever, and the author believes that in these cases the disease is a typical streptococcus or staphylococcus infection. One series, fairly typical of those diphtheroid conditions referred to infected milk, is the following, in which the milk was believed to be that of cows suffering from cowpox. At Fettes College, Edinburgh, an epidemic occurred, characterized by malaise, headache, anorexia, occasionally "sickness" and epistaxis, and usually, furred tongue and foul breath. Examination showed the tonsils and posterior wall of the pharynx bright red with, constantly, follicular exudation There was considerable swelling of these parts, and also of the uvula and soft palate, but never any deposit upon them, though there was sometimes a considerable patch upon the tonsils. Albuminuria was infrequent. The duration of the acute stage was usually seven days. A peculiar symptom was the involvement of the uppermost of the chain of lymphatics behind the sternomastoid, this always taking place several days after convalescence had set in, and forming a large, brawny swelling, which subsided slowly without suppuration. The disease appeared not to be contagious, but a first attack conferred an almost absolute immunity. This epidemic ceased upon the milk being served boiled, and reappeared when the boiling was discontinued. Attention is directed to the almost total absence of scarlet fever in Japan, where milk is only used as a medicine, and the infant mortality under one year for Tokio is cited as 535 per 100,000, compared with 603 per 100,000 for Washington, the latter figure, however, not corresponding with that cited above for the same city. In the milk of cows suffering from puerperal fever, micrococcus pyogenes aureus has been found, and the milk has caused vomiting and diarrhœa. There is reason for believing that septicæmia neonatorum may be derived from germs conveyed through the milk, as Escharich has found pyogenic germs in the milk of twelve out of thirteen puerperal-fever patients, and Karlinski has demonstrated the staphylococcus in the milk, and in the intestinal contents and the blood of the infant. The milk of cows suffering from foot and mouth disease has caused aphthous stomatitis, the following being the principal symptoms: Fever, pains in the head and limbs, swelling of the mucous membrane of the tongue and mouth, with the formation of vesicles, which subsequently ulcerate, the ulcers being accompanied by a burning pain; and vesicular skin eruptions on the hands and legs, which subsequently ulcerate, the ulcers healing slowly. In some epidemics, shivering, giddiness, an inclination to vomit, a yellowish-gray color of the skin, obstinate constipation, hoarseness, looseness of the teeth, intense fetor of the breath, and alarming swelling of the mucous membrane of the mouth were observed. There is no absolute demonstration that milk has conveyed anthrax, pleuropneumonia, rabies, and tetanus, though suggestive cases are not lacking, and the bacillus anthracis has been found in the milk.

Concerning the transmission of tuberculosis from cattle to man, apart from cases dating from the first half of the last century (notably the thoroughly-studied series of Klencke), the following data are adduced: Of the 1,013 replies from physicians to Ernst's question whether they knew of cases of transmission, 895 were in the negative; eight reported transmission from mother to child; eleven reported cases of infection through cow's milk, and sixteen reported suspicious cases. Of fifty-four replies to the same question from veterinarians, fourteen reported positive cases, and nine, suspicious cases. Johne reports the case of a child of healthy ancestry, who died, aged two and a half years, of miliary cerebral tuberculosis, after feeding on the milk of a tuberculous cow, the other children remaining healthy. Hermsdorf relates the case of a girl who died, aged fourteen, of tuberculosis of the larynx, ileum, and cæcum, who had been in the habit of drinking warm the milk from a tuberculous cow. Leonhard mentions a family in which the children contracted tuberculosis soon after weaning. Tuberculosis was found in the cow, and the next child remained healthy. He also mentions two cases of tuberculous meningitis traced to the milk of a tuberculous cow. Demme, Sonntag, Meyerhoff, Stang, Schöngen, Herterich, and Uffelmann report cases of infection under similar conditions. Epstein finds that children of consumptive parents rarely develop the disease when provided with a healthy wet nurse, and attributes the frequency of intestinal tuberculosis to infected milk. Brouardel reports the death from tuberculosis of five out of fourteen girls in a boarding house, after drinking milk from a tuberculous cow, and he cites the cases of seven other girls in a convent, believed to have been infected in a similar manner.

Instances of cholera occurring from the use of milk which had been infected through dilution with infected water and in other ways are cited. Of 195 epidemics of typhoid fever, due to the milk supply, in 148 there was evidence of the presence of typhoid at the farm or dairy. In sixty-seven it was probable that the milk was infected through soakage of the germs into the well water used for rinsing the cans, and in sixteen intentional dilution with infected water was a matter of evidence. In four ice cream prepared on infected premises was the carrier, and in one of these, sewage germs were found in the cream. In seven instances the infection was spread through milk delivered at creameries. In twenty-four cases the dairy employees also acted as nurses, and in ten instances the dairy hands had typhoid fever, but continued at work. In seven instances the infection was attributed to the cows drinking of or wading in infected water. As regards scarlatina, ninety-nine epidemics are recorded. In sixty-eight cases the disease prevailed at the farm or dairy. In six instances the dairy hands either lived in or visited infected houses. In seventeen instances the infection was doubtless conveyed by persons connected with the milk business while suffering from the disease, and in at least ten cases by persons nursing the sick. In three cases the milk had been kept close to the sick room. In one epidemic the milk was distributed by two milkmen, one of whom had scarlet fever at his house, and all the cases (fifteen or sixteen) occurred on his route, and none on that of the other. In nineteen instances the disease was referred to disease of the cows; puerperal conditions, four times; inflammations of the udder or teats, nine times; and loss of hair and casting of the skin, six times. Of diphtheria epidemics, thirty-six are reported. In thirteen instances the disease existed at the farm or dairy. In twelve instances it was attributed to inflammatory and ulcerative conditions of the udder. Of the 330 epidemics reported, 243 have been reported by English authors, fifty-two by American, fourteen by German, and eleven by Scandinavian. This is probably due to the use in England and America of unboiled milk.

An Instance of Marked Virility is reported from Barnegat, N. J., where a man who remarried at the age of eighty-two years has had two children since, the youngest having just been born when the father was eighty-six years old.

THE VACCINATION OF PORTO RICO: A LESSON TO THE WORLD.

FROM time to time the medical press has had occasion to sound a note of warning as to the dangers which must inevitably follow relaxation in the matter of compulsory vaccination. In the *Pacific Medical Journal*, Major Azel Ames, late Brigade Surgeon, U. S. V., and Director of Vaccination in Porto Rico, speaks in no uncertain tones. Especially, however, he brings forward his experience—that is to say, *facts*—which forms an object lesson on a vast scale. As the author remarks, there is urgent and grave need, at the present time, for just such a lesson, as is only too evident in view of the recent history of legislation inimical to vaccine protection, both here and abroad, a notable instance being the emasculation of the British law by the "conscience clause," with the consequent large increase in the percentage of infant mortality from variola. The need is, moreover, alarmingly attested by the recent pandemic of smallpox on both sides of the Atlantic. It is only by such clear and incontestable facts that the people can be brought to see the necessity of compulsory vaccination; and the need of their seeing it was never greater, for there never was a time when, through the increased intercommunication of children in the schools, and the increase of house-to-house occupations, the commingling between all classes of the population was so great. Major Ames claims, and, as we believe rightly, that his experience furnishes "the absolute demonstration that comprehensive compulsory vaccination, properly conducted, will alone certainly eradicate smallpox from *any* region or people, as established conclusively in Porto Rico in 1899."

It is impossible to convey in abstract the full force of this excellent article, but the results speak for themselves. When the Spaniards left the island in October, 1898, smallpox was endemic; in December it was epidemic; in January, 1899, it had "honeycombed" the island; and by February there were 3,000 recent cases, and the disease was "spreading at a gallop." In February systematic, compulsory vaccination was begun with fairly equal efficiency in all parts of the island. Vigorous prosecution for four months, until July 1, resulted in 860,000 vaccinations out of a population of 960,000. The work then ceased, completed, and the disease had practically disappeared. In the two and a half years since then, the mortality has been but two per year as against a former yearly average of 621. The author well says: "Can any *honest*, intelligent person doubt, in the face of these indisputable, easily verified facts, *what* it was that in *four* short months drove smallpox from its wide and long-time reign in the island, and has since kept it out? Vaccination alone did it, and will do it effectively wherever compulsory legislation, properly enforced, secures its benefits to all." When first taken hold of, the problem presented the following exceptional aspects: The whole island was involved, and whenever the disease was for a time repressed in the towns, the country districts continually served as feeders to the centers of population.

Among the factors especially favoring the spread of the disease were the tremendous headway it had attained and the numerous centers of contagion; the comparative indifference to it on the part of the natives; the absence of systematic sanitary authority and oversight, rendering detection of cases difficult, especially as, on account of antipathy to removal from home, the natives habitually concealed the disease; and the density of the population, the constant passing back and forth between country and town, and the uncleanly character of the habitations and of the habits of the people. Among the conditions exceptionally hampering measures of restriction and control were the great difficulty in isolating the hundreds of cases occurring simultaneously over a great and inaccessible area, the absolute impossibility of securing isolation in the crowded and thickly-set homes; and the great insufficiency, proportionately, of the medical help. The only conditions exceptionally favorable to the suppression of the disease were its limitation by the seaboard, plenitude of authority, civil and military; a sufficient supply of cattle for vaccine generation; and the fact that a large proportion of the population had had the disease. Some of the conclusions arrived at, as a result of the vaccination work, possess general interest and importance. The author says that be the reason what it may, the fact was conclusively demonstrated that vaccine lymph, especially when glycerinated and in tubes, did not retain its efficacy, when exposed, even briefly and without great variations of temperature, to the change from a temperate to a tropical climate. Further, in their work, the glycerinated virus was found to have nothing to recommend it, and the glass tubes proved "worse than useless." In field work nothing was found so satisfactory as the ivory "point," whether for taking virus or for vaccinating animals or people. Concerning the question of transmitting diseases along with vaccination, the author's experience was decisive. He says: "There is every warrant for positively asserting that although syphilis, tuberculosis, elephantiasis, and tetanus are common in Porto Rico, in no case has it followed that any of them, or any other disease, bovine or human, was imparted to an individual by the process of vaccination." Thus with 818 cases of tetanus occurring in seven months of 1900–1901, out of 860,000 vaccinations, only one case of tetanus occurred, in an infant. Vaccination was always practised, with the sharp edge of the ivory point. Cleanliness and a light antiseptic dressing proved an all-sufficient safeguard against infection, and hot water, freely applied, sufficed for the reduction of undue inflammation, even in the worst and dirtiest regions. "Bad arms" were invariably the result of carelessness and dirty habits. In no instance did serious infection occur. Of the vaccinations 87½ per cent. were successful. Twenty of the successful cases were in persons "seamed and furrowed" from former confluent smallpox. A few cases of smallpox occurred in those who had the disease before. That the protection of vaccination "wears out," was determined "beyond cavil and by abundant evidence." Numerous cases not vaccinated until after exposure incurred smallpox, but in every case the vaccination clearly operated to modify the attack, and in some cases it caused its abortion, usually in the third stage. Many hundreds whose vaccination "took" claimed, with apparent truth, that they had been repeatedly vaccinated without success. In seventy-two persons in one place, whose arms had been washed with bichloride solution, vaccination failed, and upon the bichloride solution being omitted the whole seventy-two were revaccinated. Vaccination repeatedly failed in not a few young children whose mothers had had smallpox during gestation, and a few cases occurred in which the failure appeared to be due to the vaccination of the mother during gestation. Among those successfully vaccinated in recent years no death occurred from variola, and in few cases was there much disfigurement.

CHILD LABOR IN THE UNITED STATES.

Although the United States claims—and rightly to be in the van of civilization, there yet remain in certain parts of the country many survivals of mediævalism. In but few civilized lands at the present time are children of a tender age permitted to work in factories and mines. Nevertheless, in America such a condition of affairs exists. In the mines of Pennsylvania and elsewhere, young children labor underground, in Southern factories they work, while in parts of the West their services are utilized; indeed, it is declared that in most large manufacturing districts child labor is common.

The Illinois Federation of Women's Clubs through its Industrial Committee has recently delivered itself of some weighty pronouncements on the matter, so far as Chicago is concerned.

The New York *Tribune*, November 16, quotes from the report of this committee. The following sentence therefrom serves as a text upon which an incisive and convincing sermon is preached: "The Illinois factory child, trained neither in the schoolroom nor the workshop, promises in coming maturity to be little more than an addition to the mass of wretched, helpless, unskilled labor." The report goes on to say, "Many occupations are found to threaten mutilation and disease. In cigar factories the boys and girls employed become saturated with nicotine, and during some processes are obliged to stay in rooms into which no fresh air can be admitted. There are frequent accidents among the children employed around the dangerous machines used in paper box making. In paint works, soap works, chemical works, rubber works, and photograph shops absorption of poison through the skin is unavoidable. Many young boys in sweatshops are button-holers and every one develops curvature of the spine sooner or later. Those who run foot-power machines develop tuberculosis of the lungs or intestines. The little "hand girls" develop crooked backs over their hemming, felling, and sewing on of buttons, or tuberculosis or other disorders over the foot-power machines." A long list is given of various employments in which children serve and which are unhealthy in a high degree. New York, Ohio, and New Jersey all have laws preventing the night work of children. Illinois also permits children to work who cannot read in any language, who have never attended any school. She demands no educational test before beginning work, such as is demanded in twenty other States. The number of child laborers has doubled since 1897. There are now twenty thousand children under fourteen working in Illinois factories, mainly in Chicago.

This is a state of things which for the interests of the nation at large it would be well for legislators to take cognizance of and to pass laws to regulate child labor. The Committee of the Illinois Federation of Women's Clubs has designed a bill to prevent the employment of children under fourteen, to prevent night employment of children, and to reduce illiteracy. The enactment of such laws throughout the country would be a great public boon.

THE CONGENITAL FACTOR IN HERNIA.

The *Hospital*, in its issue of November 8, devotes that part of the journal reserved for discussion of progress in surgery to a consideration of the different forms of hernia.

R. Hamilton Russel, in the *Lancet*, May 31, contributed an article on congenital hernia. The views set forth by the author are: (1) that oblique inguinal hernia is always caused by the presence of a congenital sac; (2) that there is no evidence that congenital weakness of the abdominal wall is a factor in causing inguinal hernia; (3) that any such weakness met with there is acquired and due to the existence of a hernia and the use of a truss; (4) that complete removal of the sac in the absence of such acquired weakness will not be followed by recurrence, and (5) that the causes of recurrence are: (*a*) the above-mentioned weakness, (*b*) incomplete removal of the sac, and (*c*) traumatism, from faulty operative methods. The writer further holds that these views apply with as much weight to the hernia of adults as to those of children. Dr. Russel is opposed to the generally-accepted opinion that congenital weakness of the abdominal wall is primary and the development of a hernial sac secondary. The occurrence of direct inguinal hernia is attributed to the laxity of the peritoneum in the inguinal region, and this form of hernia seems to occur suddenly and independently of the presence of a preformed sac. This is the only form of hernia to which the name of rupture can be said properly to belong.

Hernia of the sigmoid, rare in children but frequent in adults, is considered to be due to the processus vaginalis in such cases joining the peritoneum close to the attachment of the mesosigmoid, and to the portion of peritoneum to which the sigmoid is attached, for that reason, descending as soon as the neck of the sac becomes sufficiently distended.

Just as inguinal hernia is attributed to the existence of a congenital sac so likewise are femoral, obturator, and ischiatic hernias. The formation of congenital sacs in these other situations, it is suggested, is intimately associated with the development of blood-vessels and their passage through the parietes.

THE STRONG DRINK QUESTION.

A concerted movement is at the present time being made in the interests of temperance, in both Great Britain and the United States. The crusade against drink is headed by prominent churchmen and social leaders. The fact is now clearly recognized that indulgence in alcohol is sapping the strength of almost all civilized countries, and that the more sober a people are the better will they prosper in every way.

The *Quarterly Review*, October, discusses the various modes suggested to solve the drink problem. Referring to a book on the subject recently written by Joseph Rowntree and Arthur Sherwell, the *Review* says: "In Norway wise legislation has converted what was once the most drunken nation of Europe into the most sober. It was in 1865 that the 'Company System' was first established in the town of Gothenburg, whence by private effort and State encouragement it has spread over the Scandinavian peninsula. Its underlying principle is the elimination of private profit from the retailing of alcoholic drink. The houses and bars where drink is retailed are held in monopoly by private companies, constituted under the self-denying ordinance of a strictly limited return to shareholders; and these companies appoint agents for the retailing of drink, under conditions of remuneration which exempts them from any personal interest in the amount of alcohol trade that passes through their hands. Among the advantages attributed by Messrs. Rowntree and Sherwell to this system, the following appear to be most conspicuous: a dangerous trade is placed under efficient control; evils such as gambling, drinking on credit, the pushing of the sale of drink by the publican, disappear; a source of corruption detrimental to social progress is removed; a divorce is effected between drink-selling and politics, and the way made easy for further reform, for where no personal interest is concerned, political propagandism ceases to find a reason for its existence; illicit drinking and the 'club' difficulty disappear, the drink traffic being kept above not driven below the surface; and, finally, large profits that otherwise go to the trade are, after satisfying the modest conditions of interest on shareholders' capital, made available for furthering the cause of temperance by establishing counter attractions to the temptation to drink. The practical conclusions of value to be deducted from the experiments in Scandinavia are thus stated:

'The first, the bed-rock upon which any fabric of effective licensing reform must be built, is to take the trade out of private hands. So long as the private interest of the seller runs counter to the interest of the State, so long will the effort of the State to restrict and control the traffic be baffled. The second is that the trade, when taken out of private hands, shall be worked, locally, not by the State, and should be subject to no other State control than that which is necessary to secure honest administration and the complete carrying out of the conditions determined by the statutory law under which the localities carry on the traffic."

MALARIAL DISEASES IN THE UNITED STATES ARMY.

The report of the Surgeon-General of the United States Army for the fiscal year ending June 30, 1902, states that in the army, as a whole, during the calendar year there were reported 35,180 cases of malarial disease, with a death rate of only 0.59 per thousand of strength.

One of the most important results arrived at from the examination of the blood for the malarial parasite by Contract Surgeon Charles F. Craig, U. S. Army, in the general hospital, Presidio of San Francisco, Cal., has been the great number of cases of latent and masked malarial infections discovered in soldiers returned from the Philippines. Although the fact is well known that malarial infections may remain latent for a long period in some instances, the percentage of cases exhibiting this latency, so far as reported, has not been as large as the results obtained at this hospital seem to show. Of the 1,082 cases in which malarial parasites were demonstrated in the blood, 219 were cases of masked or latent malaria. Thus of the 1,082 cases, 20 per cent. were of this class of infections.

In twenty cases diagnosed as chronic diarrhœa malarial parasites were demonstrated, and in all these the infection was latent. Symptoms of diarrhœa were present in all, but there was no rise in temperature, and no symptoms which could be interpreted as being malarial in character.

Treatment by quinine in these cases quickly caused the disappearance of the parasite from the blood, and, as a rule, resulted in the general betterment of the patient's condition, so that, as the cases have to be classed as latent on account of the absence of symptoms, the improvement in the patient indicates that the malarial infection has some influence in the progress of the diarrhœa.

Cases in which symptoms of pulmonary tuberculosis were clearly defined, also on examination exhibited the presence of malarial parasites in the blood.

This is especially true of cases originating in the tropics, the emaciation being more extreme and the pulmonary symptoms more apparent than in cases originating in the Temperate Zone.

The report rightly lays emphasis on the importance of blood examination in all cases of disease originating in the tropics or in localities which are known to be malarious. The numerous cases observed at the general hospital, Presidio of San Francisco, amply demonstrates the fact that a malarial infection complicating any disease process invariably injures the patient's chances of recovery, and its elimination, greatly facilitates recovery. Not only is this so, the report declares, but cases have been observed in which the discovery of the malarial infection undoubtedly saved the patient's life. The discovery of cases of estivo autumnal malaria is especially important, as it is this form of the disease which may become at any time pernicious and may cause death within a few hours.

Any case of sickness incurred in tropical regions should be examined for malarial parasites, as the presence of these in the blood cannot but hinder the recovery of the patient, whatever other disease he may be suffering from.

Growth by Electricity.—Dr Maurice Springer read an interesting paper at the Academy of Medicine this week on animal growth, specifying four elements of nutrition having most effect in inducing organic development—namely, lecithin, potash, oxides, and water. The doctor also pointed out that electricty is a powerful agent in the development of growth. By applying a faradic current to certain muscles and joints of children both growth and increase of weight have been obtained.—*New York Herald*.

The Importance of the Consideration of Habit in the Treatment of Sleeplessness.—William Wormley says that as pointed out by McFarlane, each bodily organ has its habit. Sleep is the period of repair, but the requirements of the tissues vary greatly during the stages of growth, development, maturity, and decadence; consequently the depth and duration of sleep vary greatly too. Every one has a "sleep habit" normal to himself which should be studied carefully. Does the patient fall asleep quickly, when and how does he awake, is the wakefulness associated with restlessness, discomfort, or unpleasant sensations? Consider the cause of the sleeplessness—is the patient suffering from worry, from over indulgence in alcohol or tobacco, or is there a hypersensitiveness to external stimuli due to neurasthenia or to gouty or rheumatic conditions? The author suggests a number of methods for overcoming the habit of sleeplessness, and deprecates the use of hypnotics. A punch of hot Jamaica rum taken just as one is getting into bed, and made as hot and as strong as can be borne, has overcome many stubborn cases of sleeplessness. It can be gradually withdrawn, as it will not be needed after a week or so.—*St. Louis Medical Review*.

News of the Week

The Cartwright Lectures for 1902.—The Cartwright lectures of the Alumni Association of the College of Physicians and Surgeons (Medical Department of Columbia University) will be given in the hall of the Academy of Medicine, on December 17, 29, and 30, at 8.15 P.M., by Dr. Richard C. Cabot of Boston. The subject of the first lecture will be "A Study of the Urinary Analyses and Post-mortem Findings in 500 Cases of Disease Affecting the Kidneys;" that of the second lecture, "A Clinical Study of the Action of Alcohol in Disease with Special Reference to Its Effect on the Circulatory System;" and of the third lecture, "Truth and Falsehood in Medicine; an Experimental Study."

A Proposed Foreign Service Medical Corps.—A bill has been prepared, for introduction into the present Congress, to create a foreign service medical corps in the medical department of the U. S. Army. The purpose of the bill is to establish a permanent medical corps similar to the British East Indian Medical Service, whose duty it will be to serve the military and civil services of the United States in those countries, which, while under the United States Government, are separated, as to their people and country, from the United States proper. It is felt that properly qualified medical men will not go in sufficient numbers to the tropics to enable the officials and other civil employees of the government to obtain that expert medical attention which they would receive in the United States, unless incentive is offered them. Men who have not devoted time and study to tropical surgery and medicine cannot attain to that proficiency which will be given by those who are specially trained for this work. The provisions of this measure at once place a body of men trained in medical military tropical service at the command of the United States, to be used by either the civil or military authorities as the necessities may require. With a fixed tenure of office, and provision for old age, a better quality of medical service may be had for less cost. These men are needed particularly in the care of the Constabulary, and other native forces, and in the management of epidemic disease, falling under the jurisdiction of civil governments, as well as to replace in the army those volunteer surgeons who are soon to be discharged by expiration of law, and the contract surgeons who are now employed in the tropics.

The Army Death Rate.—In the report of the the Surgeon-General of the Army to the Secretary of War for the fiscal year ending June 30, 1902, on page 45, the death rate from all causes for the year 1901 is incorrectly given as 19.94 per thousand. It should read 13.94 per thousand. These figures are correctly given in Table 1, page 148.

The University of Michigan.—Two new buildings are being erected near the University Hospital, Ann Arbor. One, the psychopathic ward, is to cost fifty thousand dollars. The appropriation was obtained from the State Legislature largely through the efforts of Dr. William J. Herdman. The first stages of insanity will be studied here. The State has generously provided for the maintenance of the ward. The late Mrs. L. M. Palmer bequeathed $20,000 for the establishment of a ward for children. The building, which is to be known as the "Palmer Ward" is fast approaching completion. Mrs. Palmer also bequeathed $15,000 as an endowment for the maintenance of this ward.

A National Plague Conference.—At a meeting of the Connecticut State Board of Health, held last week in New Haven, it was decided to request the Surgeon-General of the Public Health and Marine-Hospital Service to call a convention of State boards of health for the purpose of devising measures for preventing a spread of bubonic plague. At the convention of health authorities held in New Haven three or four weeks ago it was announced that if five States made a request for such a convention the surgeon-general would call it. Connecticut is the fifth State. The board condemned the manner in which the plague outbreak in San Francisco has been handled, the Governor, Mayor, and such health officers as these and other politicians could influence conspiring to deny the existence of the disease.

Congress of American Physicians and Surgeons.—The sixth triennial meeting of this congress will be held in Washington on May 12, 13, and 14, 1902.

An Illegal Practitioner Fined.—A masseuse of this city, who was recently brought to trial on complaint of the Medical Society of the County of New York, has been fined $150 for practising medicine without a license. She had a diploma from one of the defunct bogus medical schools of Chicago.

Dr. Ogden C. Ludlow has been appointed visiting physician to St. Joseph's Hospital in this city.

The "Index Medicus" and the Carnegie Institute.—The announcement is made that the publication of the *Index Medicus* will be revived and put upon a secure foundation by the trustees of the Carnegie Institute.

Western Surgical and Gynecological Association.—The twelfth annual meeting of this society will be held at St. Joseph, Mo., on December 29 and 30, 1902, under the presidency of Dr. James E. Moore of Minneapolis. The secretary is Dr. George H. Simmons, 61 Market street, Chicago. The preliminary program contains the titles of a number of papers on interesting topics.

The Prevention of Pneumonokoniosis.—The Chamber of Mines of Johannesburg, South Africa, has offered three prizes of the value of $2,500, $1,250, and $500 respectively for the three most practical suggestions looking to the prevention of miner's phthisis. The committee of award will comprise two members of the Transvaal Medical Society, two members of the Mine Managers' Association of the Witwatersrand, two members of the Mechanical Engineers' Association of the Witwatersrand, three consulting mining engineers to be chosen by the Chamber of Mines, and two practical rock-drillers, to be selected by the Mine Managers' Association.

Explosion of a Vial of Nitrite of Amyl.—Dr. John J. Abel of the Johns Hopkins University was the victim recently of a peculiar accident which might have had very serious consequences. A bottle of amyl intrite which he had in his hand exploded, cutting his wrist, and the fumes of the drug nearly overpowered him before he could reach the open air. An assistant, who was with him in the laboratory at the time, was similarly affected.

High Death Rate in European Armies.—General André, the French Minister of War, in a recent statement made in the Senate, drew attention to the insanitary condition of the army, saying that since 1870 Germany had only lost 13,000 soldiers from disease, while France had lost 99,000 from the same cause. Tuberculosis and typhoid fever, he said, are the principal factors in this high mortality rate. Commenting on this report, the *Daily Express* of London declares that the deaths in the British

Army exceed those in the army of any first-class Power; the average annual deaths being only 300 less than in the French Army, although the British Army is only one-third as large as that of France. This mortality is largely attributed to unhealthy barracks.

Superintendency of the King's County Hospital.—Dr. Jesse P. Duryea has resigned from the position of general medical superintendent of the Kings County Hospital and almshouse, to take effect about December 10. Dr. John F. Fitzgerald, superintendent of the Rome State Custodial Asylum, has been appointed his successor.

The Philadelphia Neurological Society.—At a stated meeting, held November 25, Drs. D. L. Edsall and R. S. Lavinson presented "a case of senile chorea." Dr. Alfred Gordon read a paper entitled "A Note on Traumatic Syringomyelia, with the Report of a Case Presenting Sensory Disturbances Affecting One Limb and Trophic Changes in the Subcutaneous Tissues of the Entire Limb." Dr. Wm. G. Spiller read a paper entitled "Traumatic Lesions of the Spinal Cord without Fracture of Vertebræ." Dr. F. X. Dercum reported a case of ataxia following injury of the frontal lobe of the brain, in which marked improvement followed operation. Dr. John K. Mitchell reported a case of familial tremor of the head.

Foot-and-Mouth Disease in New England.—Secretary of Agriculture Wilson has notified the managers of railroad and transportation companies of the United States, stockmen, and others, of the establishment of a quarantine on cattle, sheep, and swine in the New England States, and has forbidden the exportation of such animals from the port of Boston until further orders. Recent investigations by the Department of Agriculture have shown foot-and-mouth disease prevails extensively in Connecticut, Rhode Island, Massachusetts, and Vermont. Dr. Mohler of the department, Dr. Leonard Pearson of the University of Pennsylvania, and Dr. James Law of Cornell recently visited the infected districts and united in a recommendation that in order to prevent the further spread of the disease a quarantine should be established immediately. An order quarantining the Brighton Stock Yards, which is the clearing-house for cows for the Boston milk district, and to which the foot-and-mouth disease has been traced, was issued last week by the Massachusetts Commissioners. It is believed, however, that the epidemic originated in Rhode Island. The Connecticut authorities deny that the disease exists among cattle in that State. The last previous epidemic in New England, which occurred about thirty years ago, was traced to some cows brought from Canada.

The Norwegian Hospital.—Ground was broken on November 24 for the new building of the Norwegian Hospital, at Fourth avenue and Forty-sixth street, Brooklyn. M. H. Hegge, President of the Board of Trustees, delivered an address, in which he discussed the work of the institution. Sister Superio Mathilde broke ground with a spade. The benediction was pronounced by the Rev. T. Castberg. The new building is to cost about $140,000.

Award of the Nobel Prizes.—The Nobel research prize has been awarded to Major Ronald Ross of the Liverpool School of Tropical Medicine in recognition of his investigations into the mosquito-malaria theory. Three other Nobel prizes were awarded, as follows: Natural science and chemistry, Dr. Emil Fischer of the Berlin University; physics, Dr. Arrhenius of the Stockholm High School; medicine, Dr. Finsen of Copenhagen, the originator of the form of phototherapy which bears his name. Each prize is of the value of $40,000.

Removal of a Health Officer for an Incorrect Diagnosis.—The Town Health Officer of Baltic, Conn., was removed from office a short time ago because he reported to the County Health Officer that two persons suffering from smallpox had only trifling skin diseases. There are now twenty-five cases of smallpox in the town.

Professor I. Neumann of the University of Vienna is now in the last year of his professorship, having reached the age limit. His successor in the chair of syphilis and diseases of the skin will be Professor F. Mracek, who is now an extraordinary professor of the same subjects. Dr. Mracek will be fifty-five years old in April.

The American Association for the Cure of Inebriety will hold its thirty-second annual meeting in the hall of the Washingtonian Home, Waltham street, Boston, Mass., December 18, 1902. The first session, beginning at 2 P. M., will be devoted to a symposium on the Treatment of Inebriety. Papers will be read by Dr. Coles of the MacLean Asylum Dr. Drew of the Asylum for Insane Criminals, Dr. Ellsworth of the Washingtonian Home, Dr. Elliot of the Willard Hospital, Dr. Rodebaugh of Parkview Home, Ohio; Dr. Stearne of the Norway Sanatorium Indianapolis; Dr. Shepard of the Brooklyn Sanatorium, N. Y.; Dr. Osgood Mason of the Retreat New York City, and others. In the evening session beginning at 8 P. M., the president, Dr. L. D. Mason of Brooklyn, N. Y., will deliver the annual address. Dr. T. D. Crothers of Hartford, Conn., will read a paper on "Inebriety in Ancient and Modern Times," and addresses will follow by Drs. Marcy, Madden, Didama, Kellogg, and others.

The Philadelphia Almshouse and Hospital.—The Finance Committee of Philadelphia Councils has recommended an appropriation of $215,000, to be obtained through a temporary loan, for the purchase of a site for an almshouse, a hospital for the insane, and a municipal hospital for infectious diseases.

Subscriptions for the Virchow Memorial.—The German committee in charge of the celebration in honor of the late Professor Rudolf Virchow's eightieth birthday, has begun collecting funds for the purpose of erecting a monument in memory of that great man and physician. The following-named men in this country are ready to receive contributions, which will be duly acknowledged: Frank Billings, 100 State street, Chicago, Ill.; Thomas D. Coleman, 505 Greene street, Augusta, Ga.; A. Jacobi, 19 East Forty-seventh street, New York City; W. W. Keen, 1729 Chestnut street, Philadelphia, Pa.; Wm. H. Welch, 935 St. Paul street, Baltimore, Md.

Philadelphia County Medical Society.—At a stated meeting, held November 26, Dr. Wm. S. Wadsworth presented a specimen of ruptured ectopic gestation-sac. The pregnancy was evidently of tuboovarian type, and the sac had become lodged and adherent in Douglas's cul-de-sac. Rupture had taken place in this situation, with the escape of a vast amount of blood into the peritoneal cavity The condition had not been suspected during life a diagnosis of gastralgia and one of metritis having been made by different practitioners. Dr David Riesman presented a communication entitled "Chronic Rigidity of the Spine, with the Report and Exhibition of Two Cases Presenting Different Types." In the one case there was marked kyphosis in the dorsal region of the spine, without rigidity of the shoulder-joints and hip-joints, while in the other the kyphosis was less pronounced and rigidity was marked at the hips and knees and only less so at the shoulders. In both cases the disease had been observed for some ten years. The one, however, was in an old man in the neighborhood of seventy-five years, and the other in a comparatively young man about forty years old. In neither were noteworthy nervous symptoms present. Dr. Chas. K. Mills presented a case of spinal rigidity with similar involvement of the joints of the trunk, in a comparatively young man, who was unable to stand or move about. Dr. Wm. G. Spiller presented a case with rigidity of the spine and deformity, associated with tremor, strongly suggestive of paralysis agitans. Dr. Jas. Ely Talley presented a report of a case of splenic anæmia. The patient was a woman who had previously suffered from malarial fever with enlarged spleen in the West Indies, and in whom there subsequently developed a moderate degree of anæmia with epistaxis and persistent enlargement of the spleen. Dr. Robert N. Wilson, Jr., read a paper entitled "The Meaning and Significance of Leucocytosis."

The Late Dr. A. M. Phelps.—At a meeting of a committee appointed by the President of the Medical Board of the City Hospital on November 22, 1902, the following resolutions were passed:

Whereas, The late Dr. A. M. Phelps served the City Hospital as visiting surgeon, in a faithful and unselfish way, for upward of thirteen years, thereby contributing to its renown and efficiency, and,

Whereas, During these years of service, Dr. Phelps endeared himself to the visiting staff of the hospital, by virtue of his character, his energy and tirelessness in the work for the benefit of the hospital, and aroused in them an admiration of his skill and manifest ability.

Be it resolved, That the Medical Board of the City Hospital record an expression of its regret in the untimely death of Dr. Phelps at the zenith of a career of usefulness, and further

Be it resolved, That a copy of these minutes be sent to the family of the late Dr. Phelps, to the principal medical journals, and inscribed in the minutes of the meeting.

(Signed) JOSEPH COLLINS,
GEORGE E. BREWER,
EDWARD S. PECK.

Philadelphia Hospital.—It is proposed by the Mayor of the city of Philadelphia to remove the Almshouse and the Insane Department of the Philadelphia Hospital from their present to a new location and to designate the former the Philadelphia Hospital for the Indigent and the latter the Philadelphia Hospital for the Insane, and to reconstruct the present hospital buildings and to designate them the Philadelphia Hospital General. Already new buildings for the Children's Department and for the Venereal Wards have been erected, and it is purposed further to erect a series of pavilions for the especial treatment of cases of tuberculosis.

Obituary Notes.—Dr. MIRZA NESTOR BENJAMIN died in Dunkirk, N. Y., on November 27, at the age of fifty-nine years. He was born in Urimia, Persia, where he began the study of medicine. He came to this country when nineteen years old, and completed his medical course at the University of Vermont in 1864 afterward, serving a term as interne in Bellevue Hospital, New York. He was a veteran of the Civil War, in which he served as a surgeon. He was proficient in nine languages and made a translation of the Bible for the American Bible Society.

Dr. EDWIN GRANVILLE died at his home in Kansas City on November 24, at the age of fifty-nine years. He had long suffered from tabes dorsalis. He was born in New York City in 1843, and was the son of Dr. Edwin Granville, for many years professor of anatomy at the New York University. He himself was a graduate of the Kansas City Hospital College of Medicine in the class of 1885.

Dr. THOS. H. PRICE died in Philadelphia on November 22 of septicæmia at the age of fifty-eight years. He was a graduate of Jefferson Medical College in the class of 1876, and was at one time vaccine physician and a member of the Philadelphia Emergency Corps.

Dr. CHAS. P. LEONARD of Niantic, Conn., died on November 22 at the Medico-Chirurgical Hospital in Philadelphia, where he was a resident physician, in the sequence of an operation for appendicitis. He was graduated from the Medico-Chirurgical College in the class of 1902.

Dr. HENRY MELVILLE SMITH died at his home in South Orange, N. J., on November 28, from cardiac disease, at the age of fifty-one years. He was born in Meredith, N. Y., and was graduated from the College of Physicians and Surgeons in this city in the class of 1871. He practised for many years in Jersey City before going to South Orange.

So-Called Scarlatiniform Eruption Following the Serum Treatment of Diphtheria.—Karl Leiner has observed six cases, all of which presented the following characteristics: (1) The eruption first appeared within five days after the injection of the antitoxin; (2) It was followed by a typical lamellar desquamation; (3) A glomerulonephritis was a frequent sequel; (4) Other children in the same room which had not been in any way sick or inoculated with antitoxin developed a similar eruption after exposure to these cases; (5) The contagium was very tenacious, since a formalin disinfection of the apartments was not followed by a disappearance of the infection; (6) The eruption and desquamation was most abundant in the region of the site of inoculation, a circumstance which greatly reminded one of surgical scarlet fever. All of these facts show that in these cases a genuine scarlet fever was present.—*Wiener klinische Wochenschrift.*

The Autointoxications of Pregnancy.—W. A. Potts regards as causes of this class of maladies flatulency and constipation, they leading to toxic influences and frequently causing abortion. Pernicious vomiting is another result of toxæmia. Colitis and appendicitis, ptyalism, cramps, phlebitis, and chorea, are all toxic manifestations. As regards eclamptic seizures, the author says that (1) all cases of eclampsia are found to have recently suffered from constipation, generally of extreme degree. (2) All remedies which have met with any general measure of success are remedies either of elimination or of dilution of toxins. (3) In 85 per cent. of cases of eclampsia examined post mortem, the kidneys, which are the safety-valves of toxin elimination, are found to be diseased. (4) The only other lesions frequently found post mortem are in the liver, the organ chiefly concerned in the metabolic processes, and lastly, serious disease of organs other than the kidney and liver does not predispose to eclampsia. The obvious consequence of all the foregoing is to bring the eliminative plan of treatment to the front and to place greater reliance upon it than upon all other measures combined. Potts advises also the use of thyroid extract as increasing the excretion and greatly stimulating metabolism.—*Birmingham Medical Review.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HONORS—GORDON COLLEGE—KOCH'S VIEWS—GENEROUS GIFTS TO MEDICO-CHI—POISONOUS ICE CREAMS—BACTERIA OF LONDON AIR—STREPTOTHRIX—KING'S COLLEGE—SMALLPOX

LONDON, November 14, 1902.

A HEAVY shower of honors fell on the King's birthday, and a few of the drops sprinkled the profession, viz., C. B. for Inspector-General Woods and Mr. W. H. Power; a C.M.G. for W. H. W. Strachan, Chief Medical Officer, Lagos; M.V.O. for Drs. Hewitt and D. J. Mackintosh; C.I.S.O. for Dr. McNaughton of the Scotch Prison Service.

Dr. Andrew Balfour of Edinburgh is going out as director of the chemical and physiological laboratories at the Gordon Memorial College, Khartoum, which was opened on Saturday by Viscount Kitchener. These laboratories are equipped with the most modern appliances, and are the gift of Mr. H. S. Welcome, who recently visited the Soudan. Dr. Balfour will have abundant opportunities for research, and we may look for important results, especially in the field of tropical pathology.

There have been persistent rumors that Koch had abandoned the position he took up two years ago, that human and bovine tuberculosis were not interchangeable. But the reports of the Berlin Congress received here show that these rumors have no foundation in fact, and they seem to have arisen from inaccurate statements in French newspapers. Professor Koch repeated that of all the cases of alleged infection of cattle not one could bear all the tests of scientific examination. Yet he scarcely claims perfect immunity for man from bovine infection, as he admits that he has seen instances of such communication, but so seldom, that he thinks the money spent on regulations against the sale of diseased milk and meat would be better devoted to the establishment of sanatoria—an opinion which meets with no support here.

The Royal Medical and Chirurgical Society has received a very handsome and useful present from a donor who wishes to remain anonymous, and who is not even a member of the profession. This gift is an epidiascope, with all the accessory apparatus, worth about £150. This will enable demonstrations to be given of a superior kind to the lantern illustrations. By it colored representations of opaque objects can be thrown on the screen quite as well as transparent ones. Jar specimens, bones, or the limb of a living person can be thrown on the screen and examined in a magnified illustration; so, too, can charts, tables, graphic records, and other objects. An appropriate resolution of thanks to the donor for his valuable and practical gift was passed.

The recently passed law as to the sale and manufacture of ice creams has been put in force with energy by some of our authorities. The need of this legislation was notorious, and has now been placed on a scientific foundation by Dr. Klein, who has just read a paper before the Pathological Society, in which he shows how frequently varieties of bacillus coli are present in ice creams offered for sale. His investigation of samples sent to him by the M. O. H. for the city, and others, shows that it is not only Gaertner's bacillus, but other varieties, that give rise to the attacks of acute gastroenteritis which have been observed. In the Carlisle and Portsmouth outbreaks, after eating meat pies, a virulent variety of bacillus coli, which certainly did not belong to the Gaertner group, was found. Dr. Klein detailed the characters of the B. Gaertner as recognized by bacteriologists, and contrasted them with the virulent form of B. coli which he found, and which differs much from the Gaertner group. The culture of that new form caused, on inoculation of minute doses into rodents, general hemorrhagic septicæmia, including acute gastroenteritis and peritonitis, with death within twenty-four to forty hours. After death the whole of the small intestine was deeply congested, relaxed, filled, and distended with sanguineous exudation. The subcutaneous and muscular tissues of the chest and abdomen, the lungs, the pleural and pericardial cavities and peritoneum of an animal that died in twenty hours after injection of a minute quantity of a particular sample of ice cream. The exudation was everywhere densely crowded with microbes belonging to the coli group, but differing in some respects from the typical B. coli communis. Specimens of this pathogenic ice-cream bacillus were exhibited and were shown side by side with B. Gaertner and B. coli. The virulent bacilli were found in various samples of ice cream taken on different dates from different shops, but all supplied by one maker. All were poisonous until this maker complied with the requirements of the medical officer and removed the insanitary conditions of his premises. When he had done this his ice cream became harmless. The materials employed in his [illegible] less but were manipulated by [illegible] places. Large amounts of stock [illegible] in filthy localities, and the quantity of [illegible] the day frozen, the remainder being stored [illegible]

Dr. F. W. Andrews then exhibited a [illegible] tures of the bacteria he had found in the London [illegible] phere. He used an apparatus similar to [illegible] to aspirate a known volume of air through [illegible] glass-wool and sugar in a narrow glass tube.

As a means of comparing different samples of air he considered the plan useful. It had given [illegible] results. His exhibits included about fifty species, among them cocci, sarcinæ, bacilli, streptothrices, and [illegible]. No pathogenic microbes had been detected. Dr. Klein remarked that it was strange that in air taken from the streets no bacilli coli were found. On this Mr. S. G. Shattock referred to a paper by Miss H. Chick ("Report of the Thompson-Yates Laboratory"), who had experimented in a similar way in America, and whose result was the same, so far as bacillus coli goes, for although large volumes of air were drawn through by [illegible] the organism was not detected. Dr. R. T. Hewlett suggested that they might have been killed by desiccation. Dr. Andrews, in his reply, said the number of microbes varied greatly in different samples. The average number of varieties were fifty, but sometimes he had found only two.

At the same meeting, Mr. Foulerton related five cases of streptothrix infection. In one no organisms were detected, and Mr. Foulerton thought they were dead, no young forms being seen in the pus, which was from an empyema of about three months' duration. In two others he found streptothrix hominis previously described and named by him. In another case a similar organism, but with some differences. In the remaining one (a case of alveolar abscess) he obtained a culture of streptothrix and no other organism. He considers it certain that the majority of cases of actinomycosis in man are not caused by the common streptothrix found in the ox, and that the difficulties of cultivation are the cause of the differences of description by various writers.

King's College, as I predicted, has come forward with an appeal for endowment, as University College did a few weeks ago. These two institutions are the only ones that provide for teaching in all the faculties and claim to be of university rank. King's, as I explained, is a church college, and has its theological faculty, and was established in opposition to University, which is undenominational, and does not teach divinity, and so used to be called the "Godless college." Both want to be incorporated in the new London University, and for this purpose both want money, and a good deal of it, too. I have previously told you about University's appeal. Now comes King's with a demand for a cool half-million sterling. The objects stated are to secure (1) The removal of a debt of £35,000; (2) Efficiency in laboratories and other equipments for higher education and research. (3) Adequate remuneration of the teaching staff. It is proposed to endow six chairs in the faculty of theology, thirteen in arts, eight in science, five in applied science, and four in medical science. No chair to have more than £500 a year. The half-million for which the college asks is not proposed as sufficient for its complete endowment, but only as the irreducible minimum to enable its work to be efficiently carried out as an integral part of the reorganized University of London.

As King's is only one of the colleges to be incorporated, it looks as if the new university will be a costly one before all the teaching institutions to be included have discharged their debts and set to work on an enlarged basis.

An outbreak of smallpox in a Lancashire town of 33,000 inhabitants has been traced to a barber's shop. The proprietor and his family had had the disease, had not notified it, and the business was carried on as usual. The barber declared he had no notion of the nature of the disease, and could not afford to employ a doctor. It seems incredible that he should not have sought help at a dispensary or a hospital.

THE PLAGUE IN SAN FRANCISCO

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In several medical weeklies I have noticed [illegible] comments upon the plague situation in California which are unjust to the City Board of Health of San Francisco. An instance may be found in a news item in your issue of November 15, which concludes: "These resolutions" (of the Conference of State and Provincial Boards of Health) "denounce the San Francisco authorities for failing to stamp out the disease, and especially for seeking to suppress the full facts regarding the situation." It happens that I moved the adoption of the resolutions which were proposed by the State Board of Health of

Maine, and I have an intimate acquaintance with the evidence upon which the resolutions were based.

If the resolutions did not hold up one set of men to greater scorn than can justly be aimed at any other set of men, they missed one of their purposes. The conference "*viewed with abhorrence the irretrievable disgrace of the State Board of Health of California.*" From the beginning of the story, the City Board of Health of San Francisco has maintained a consistent and honest attitude. Under a heavy fire of most malignant abuse it has not swerved for a moment from the truth. Those members of the State Board of Health who could not be bent to the will of Governor Henry Theophilus Gage were long ago removed and their positions filled by men who were definitely committed to the policy of concealment. Among those who filled the places thus vacated, the foremost is a man previously unknown as a sanitarian, but well known as a medical editor, and a professor of gynecology and abdominal surgery. With the aid of the six members of the present State Board of Health, Governor Gage and Mayor Schmitz were able to defeat both the City Board of Health of San Francisco and the United States Marine-Hospital Service. Mayor Schmitz tried to remove the City Board of Health, and to reconstruct it on the same lines which Governor Gage had successfully pursued with the State Board of Health. But the City Board of Health held on by means of an injunction, and though deprived of means to combat the plague in an effective manner, the City Board of Health has been able to keep fairly well informed of the progress of the disease, and has never prevaricated either to the people of San Francisco or to the world outside. The course of the City Board of Health has been as honorable as that of the State Board of Health has been deplorable.

The quality of the defeat administered to the United States Marine-Hospital Service may be estimated from the fact that since July 15, 1900, the Public Health Reports have published nothing on the subject of plague in California except three or four-word items at the end of each weekly résumé of smallpox, etc., in the United States. It is only fair to believe that the United States Public Health and Marine-Hospital Service is as successfully excluded as other outsiders are from a knowledge of the facts. At the New Haven meeting, October 28 and 29, the reported cases included those of October 16 and 17, of which the former is recorded in Public Health Reports of October 31, while the latter, that of October 17, has not yet been recorded, and must, therefore, have remained unknown to the Surgeon-General. While the conference was in session, a white man, living a mile away from Chinatown, died of plague, and the source of his infection remains a mystery. The case is recorded in Public Health Reports of November 7 in these words: "October 28—1 case, 1 death." Besides the case of October 17, there is indefinite information as to other cases dying between that date and October 28. No case was counted at New Haven of which the name and address were not then and there known.

The New York *Herald*, on October 30, printed an apparently authoritative statement that sixty-five white citizens of San Francisco had died of plague, twelve times as many as were accounted for in our list exhibited at New Haven. Suppose we apply this ratio to our information. We should have an estimate that 1,000 deaths from plague have occurred in San Francisco. Probably not so many deaths have occurred, but we are amply justified in believing that our information is but fragmentary. The City Board of Health of San Francisco has done its utmost to prevent the disgrace and danger which the conduct of the State Board of Health has brought upon the City and State. JOHN S. FULTON, M.D.,

Secretary State Board of Health of Maryland.

BALTIMORE, MD., November 18, 1902.

Recurrent Appendicitis.—Émile Tartière reports the case of a young man in the army who came to him for a furlough, on account of a recent operation for appendicitis. The patient was thirty-two years old, and had had two operations for appendicitis in less than two years. At the first operation an abscess was discovered, and in consequence the appendix was not removed. During the next year he suffered from dull pain in the side of his abdomen, on the march. He was obliged to enter the hospital again and have the appendix removed. The writer concludes that appendicitis can not offer cause for exclusion from the army. If it is of recent date, the patient should rest for six months or more, in order that the cicatricial tissues may become very firm. The recurrence of appendicitis is possible, even after a comparatively short interval, when the appendix has not been resected. In such cases, patients are not entirely cured, and they run the risk of another attack and of another operation.—*Lyon Médical*, November 9, 1902.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Nov. 27, 1902.

A Case of Poisoning by Thallium.—William N. Bullard reports the case of a physician who had taken thallium for purposes of experiment. The symptoms induced were slight diarrhœa, numbness in fingers and toes with extension up the lower extremities, involving the lower abdomen, the perineum, the inside of the thighs, and the inner surface of the legs. The nerves of the lower extremities were painful, and there was considerable weakness and partial paralysis of the lower extremities. Treatment consisted in rest in bed, dry heat to the limbs, and iodide of potassium in small doses. Later, when the pains had ceased, electricity was applied to the lower extremities. The condition was plainly a multiple neuritis. It followed the usual course of this affection, and the patient eventually recovered completely.

Tetany in Gastric Disorders.—Lawrence W. Strong gives the following summary of his article: (1) The condition is a symptom-complex, indicative of an increased nervous irritability, probably central in location. (2) The muscular spasm is a reflex phenomenon, set loose by some mechanical stimulation, as vomiting or lavage, with possibly a direct action, in the case of pressure and electrical stimulation of peripheral nerve trunks. The spasm, however, cannot be produced without the antecedent nervous irritability. (3) The chief factor in the diagnosis is the muscular spasm itself, affecting the arms in a characteristic manner. Other symptoms, while usually present, are not of absolute diagnostic value. (4) The etiology of the underlying nervous hyper-irritability is unknown. The theory of intoxication is the only one adequate to explain the condition.

The Normal Appendix; Its Length, Its Mesentery, and Its Position or Direction, as Observed in Six Hundred and Fifty-six Autopsies.—George H. Monks concludes as follows:—(1) Length: The average length of the appendix in men, women, and children, indiscriminately, is 7.9 cm. (or three inches); the extremes being 1 cm. and 24 cm. There is apparently no relation between the body, the sex or age of the subject, and the length of the appendix, except that children are apt to have an appendix proportionately longer than adults. (2) Mesentery: Fully one-half of all appendices have a mesentery (meso-appendix), which reaches nearly to, or quite to, the tip. Of the other half, by far the greatest proportion have mesenteries reaching as far as the middle point of the appendix, or beyond it. Occasionally an appendix has no mesentery at all. (3) Position (or direction). The commonest position or direction for the appendix is "down and in" (that is, toward the pelvis), the appendix very frequently hanging over the brim. The second commonest position is "behind the cæcum," the third is "down," and the fourth is "in". The appendix is in one of these four positions in about three-quarters of all cases.

Journal of the American Medical Association, Nov. 29, 1902.

Symmetrical Gangrene (Raynaud's) versus Endarteritis Obliterans.—J. D. Morgan gives a general description of the former affection, stating that in it the smaller blood vessels are first affected. The smaller the artery the more muscular is its middle coat, and so it is more capable of active changes in its caliber. Raynaud said the disease was due to a vicious innervation of the capillary system. The nerves, which are derived from the sympathetic system, penetrate the outer coat of the arteries to reach the muscular tissue of the medium, and these nerves, which are the dilators and constrictors of the blood supply, are controlled through their center in the spinal cord—the messages coming either from the periphery in the way of cold, heat, dampness, etc., or from the center by the toxicity of the blood or by way of higher mental and psychical impressions. It is a fact that uric acid in the blood is capable of causing vasomotor disturbance. Two clinical histories are given, one of endarteritis obliterans and the other of Raynaud's disease. Both maladies occur in middle life. Typical instances of the latter present one essential, viz., successive paroxysms of syncope asphyxia, and finally gangrene. The paroxysms are spasmodic, and there are frequent and recurring contractions of the walls of arterioles supplying the extremities attacked. Rare contributing causes of symmetrical gangrene are valvular defects and congenital narrowing of the aorta and systemic arteries. Of the modifications of sensation, analgesia is the most common. Although the sense of touch is blunted, the appreciation of heat and cold remains distinct. There is a similarity between hemoglobinuria and Raynaud's disease in that exposure to cold produces paroxysms, but in the one case the nerves and walls of the blood vessels suffer, in the other the blood and the blood-producing organs, in hemoglobinuria we often find albumin, hemoglobin, and even red corpuscles in the urine. Cases of erythromelalgia seldom lead to gangrene, and are aggravated by warmth and relieved by cold; the pain is generally present and the ulceration is confined to one extremity. Associated conditions are tuberculosis (6 per cent.) and nephritis (17 per cent.). Heredity is considered responsible for 8 per cent., and rheumatism for 7 per cent. Malarial fever seems to be associated with the disease. As far as treatment is concerned, it has been found that the iodides and nitrites are of use. Among the baths, a course of Nauheim (which can be followed here or abroad) give best results. A scrupulous regulation of all the functions of the body, with the avoidance both of alcohol and of choking the system with improper and too much food, and a regular and systematic out-door life and exercise, are the cardinal points. If gangrene should appear in endarteritis obliterans, the sooner operation is done the better the result.

Report of Four Cases of Syphilis Mistaken for Smallpox.—The cases are reported by J. F. Schamberg, who makes some remarks on the differential diagnosis of the two diseases. The cause of the confusion is the occurrence in both diseases of a papulopustular eruption, and while the cause of the malady in a given case will usually clear up the diagnosis in the course of a day or two, immediate diagnosis is not always easy. So far as differential symptoms are concerned, it may be noted that in syphilis the onset of acute symptoms is gradual, while it is sudden in variola. The rash in the former comes out for a number of days, that is, in crops; in the latter, it is generally universal at the same time. The distribution of the rash may be the same in both, but frequently there are variations observed. The pustular syphilide may involve the trunk more copiously than the face. This would be excessively rare in a well-marked smallpox. The dorsal surfaces of the wrists and hands are nearly always involved in smallpox, but may escape entirely in syphilis. The palms of the hands and the soles of the feet are always involved in severe smallpox. In moderate eruptions they nearly always present some lesions; in mild cases of varioloid they may or may not escape completely. The pustular syphiloderm affects the palmar and plantar surfaces with the greatest rarity. As to the character of the eruption, it may be stated that in the beginning the eruption may be so nearly identical in the two diseases as to make a diagnosis from this symptom alone quite impossible. It will be noted, however, that the efflorescence of smallpox presents a much greater degree of uniformity, a more uniform development of the lesions over the body than does syphilis. (It should be remembered, however, that the lesions on the face in smallpox are, as a rule, a little in advance of the eruption elsewhere.) Syphilis is characterized by an essentially multiform eruption; it is not uncommon to find small pustules, large pustules, and papules interspersed, and these in varying stages of evolution and involution. The lesions of syphilis may be grouped in the form of circles or segments of circles, particularly about the border of the hair, the commissures of the mouth, etc. The vesicles and pustules of syphilis are usually conical, and involve merely the summits of the elevation. They never become full and globular, filling the entire lesion, as do those of smallpox. The pustules of syphilis may remain small or may grow to large size, drying into brownish or greenish crusts, beneath which there is generally considerable ulceration. According to the severity of the latter, there will be seen, on separation of the crusts, a reddish brown pigmented oval or round stain or an excavated ulcer. The latter heals with the production of depressed scars. The superficial and non-ulcerated pustules frequently exhibit at their base a scaling collarette.

Medical News, November 29, 1902.

Appendicitis.—Lewis S. Blackwell declares that appendicitis has been raised to the rank of an entity on account of improved methods of diagnosis and greater accuracy in examinations. Its apparent increase to-day is due chiefly to the distinction recognized between this disease and cases of typhlitis and peritonitis disclosed by many postmortems. The gravity of the disease and its mortality rate, which is about 25 per cent. of all cases, demand the closest scrutiny at its beginning, and the greatest skill in its treatment. Besides the typical symptoms of the disease, the diagnosis is materially aided by the fact that about 90 per cent. of all inflammatory affections in the right iliac region are due to catarrh of the appendix. The location of pain and tenderness at McBurney's point is generally accepted as pathognomonic, and is the most salient factor in the diagnosis. It is admitted that one-half of the cases of appendicitis recover under medicinal treatment. This should lead to the restriction of operative procedure within legitimate bounds.

The Early Diagnosis of Intussusception.—F. Huber states that the difficulties in diagnosis, especially early diagnosis, are not great, provided the possible occurrence of intussusception is kept in mind. This early recognition is imperative, as prompt recognition of the condition improves the chances of the patient. The onset is generally sudden. If the vitality is low, the progress may be insidious. Colicky pains, recurring in paroxysms, repeated vomiting, and bloody stools are a sufficiently characteristic symptom complex of the condition. The presence of a tumor, especially if "sausage-shaped," is conclusive evidence. There is more or less prostration or collapse and change of facies. At the outset the temperature is low or even subnormal. Later, there develops more or less fever from sepsis, gangrene, or peritonitis. One or more of the usual symptoms may be late or even absent. Pain is striking. It occurs early, is sudden, of great severity, and is attended by screaming spells and other signs of great suffering. It is paroxysmal. At first the abdomen will, as a rule, be found to be relaxed and soft. Spasmodic contractions are to be noticed, and now and then a swelling can be made out. It is often a loss of valuable time to wait for the "sausage-shaped" tumor. Intussusception is no longer regarded as a borderland condition. It is a surgical disease from its very onset. To sum up, the pain is the earliest sign, followed by more or less change in the facies. Vomiting takes place, followed by the escape of blood or bloody mucus from the rectum. There is more or less collapse. There is a swelling, or rather fulness in the right iliac fossa, particularly during the attacks of colic.

New York Medical Journal, November 29, 1902.

Tent Life in the Treatment of Tuberculosis.—A. M. Holmes describes tent life in Colorado, dwelling especially on the so-called "tent cottage." Full details for the construction of the latter are given, together with such rules for governing tent life as experience has commended. Clinically summarized, the results of tent life may be thus stated: Increased appetite, improved nutrition, disappearance of cough, cessation of night sweats, improvement of sleep, increase of weight, fall of temperature, lessening of tendency to take cold, improvement in respiration, and diminution of pulse rate. Several pictures illustrate the architectural ideas of the author.

Uric Acid Bothers.—W. S. Stoakley says that when the treatment of uric-acid conditions is undertaken, success will depend on the status of normality—whether it be low or high in this particular case. The cells are feeble in some persons *a puero* and sometimes inherited. Having freed the burdened eliminants—not by storm, but rather through persuasion of the skin, with a tender touch of the kidneys and mild opening of the *viæ primæ*, it can then be seen to what eccentric degree the emunctories have wandered. They may have labored so hard that a little *rest* and a "toning up" may be absolutely required before any regular procedure as to drugs can be determined upon. In the meantime, noting the antagonisms to normality in this case, wherever they may harbor—in the earth, the air, the water, the age of the patient, the sex, the habits of the person, and all the little things in connection therewith—as men have learned what the little cell can do by way of cure in consumption, so it can do the same service in the affections under consideration, provided it is not handicapped at the time, or of anæmic birth.

American Medicine, November 29, 1902.

The Importance of a More Careful Examination and Treatment of Women after Childbirth.—B. C. Hirst says that every woman should be subjected to three examinations after labor: One at once, or within forty-eight hours, to determine the injuries of childbirth; the second before the patient leaves her room, to find out the position of the uterus; the third at the end of the puerperium, six weeks after labor, to observe the condition of all the pelvic organs and structures, the abdominal wall and coccyx, and the position of the kidneys. The various consequences of childbirth enumerated could all be prevented or cured before they have affected the individual's health. At the first examination, any injury of the cervix, the anterior vaginal wall, the posterior vaginal wall, the pelvic floor, and perineum should be repaired. At the final examination, uterine displacements, pelvic inflammations, nephroptosis, former injuries, etc., should all be corrected. These careful examinations would ensure a practical immunity from all the ill consequences of childbearing.

The Use and Abuse of Bromides in the Treatment of Mental Diseases.—A. R. Defendorf declares that the value of bromides in cases of insanity is very limited. The indications for their use would seem, according to the writer, to be mental disturbances characterized by states of nervous tension and of excitability of the motor cerebral centers. The drug finds its best use in acquired neurasthenia, in relieving insomnia and that peculiar state of inner nervous tension. In conditions of mental excitement in which motor excitation is the primary factor, the bromides are almost universally recommended. The type of mental excitement must be carefully distinguished, however. Another indication for the use of the bromine salts is in those forms of mental disease which seem to bear a close relation to sexual excitement, particularly if periodic. The writer describes several cases which present some unusual symptoms of bromism. In all of the cases exaggeration of the deep reflexes occurred, and in two were accompanied by ankle clonus. The mental symptoms were also unusual.

Philadelphia Medical Journal, November 29, 1902.

The Local Use of Iodine in Corneal Ulcers.—J. Lawton Hiers believes in regard to the preparation of iodine to be employed, that preference should be given the tincture. The eye should be first cocainized to complete anæsthesia. An eye speculum should be introduced and the ulcer scraped thoroughly with a spud. The part should be well dried, and the iodine be thoroughly applied to the ulcer by means of an applicator. The excess should be dried off, and none of the drug should be allowed in direct contact with the healthy parts of the eye. The eye should then be bathed with sterilized water or boric solution, and then treated as a recent traumatism of the cornea. The writer believes that iodine is especially adaptable to ulcers that are indoleat in type. It lessens rather than increases scar tissue. The after-treatment should vary according to the indications of each individual case. The judicious use of iodine deserves the warmest praise. In some cases two, and even three, applications have been necessary to effectd cure, but the majority of cases have readily yielded after its first employment.

Some Experiments upon the Immunization of Cattle against Tuberculosis. Leonard Pearson and S. H. Gilliland believe from the experiments here recorded, that they are justified in concluding: ()1 That after repeated intravenous injections of cultures of tubercle bacilli from human sputum the resistance of young cattle to virulent tubercle bacilli of bovine origin may be increased to such an extent that they are not injured by inoculation with quantities of such cultures that are capable of causing death or extensive infection of cattle not similarly protected. (2) That intravenous injections of much larger quantities of culture of human sputum tubercle bacilli than are necessary to confer a high degree of resistance, or immunity upon the vaccinated animal, may be administered without danger to that animal. The writers add that they are now experimenting upon young cattle to test the duration of this immunity and the extent to which it is effective in protecting cattle against infection from natural sources. They are also experimenting to find the minimum quantities of culture of nonvirulent tubercle bacilli that it may be necessary to administer in order to confer a serviceable degree of immunity, and whether it may be possible to simplify the process of vaccination by successive injections of a few cultures of progressive degrees of virulence.

The Lancet, November 22, 1902.

Pure Urea in the Treatment of Chronic Pulmonary Tuberculosis. The clinical histories of seven cases are given by S. V. Pearson, who adds a note on the action of urea From a comparison of series of cases treated according to the usual methods, he comes to the conclusion that pure urea exerts no special action on chronic pulmonary tuberculosis His general conclusions are as follows (1) Urea given by the mouth in patients with chronic pulmonary tuberculosis increases the output of urea; but the total increase in this output does not, as a rule, equal the total quantity administered. (2) Urea acts only to a slight extent as a diuretic; this action is variable and, on the whole, untrustworthy. (3) In both the output of urea and in the output of urine the effect produced by the administration of urea is more marked at first. After a time the body seems to accustom itself to the intake of urea, and tends to return to the normal output (4) Urea does not act as a cardiac stimulant.

Transplantation by Exchange.—C. R. B. Keetley refers to a case operated on by him some fifteen years ago Photographs are given of the patient as a baby and again at the age of fifteen. The girl suffered from a hairy mole on the face, which was transferred to the left arm "by exchange" that is, by transplanting the smooth white skin of the arm to the area occupied by the mole. From a considerable experience with this class of cases, the author would lay stress upon the following points: (1) Not only the outline of the flaps, but the chief points of suture should be carefully marked before the flaps are cut. (2) The knife used to divide the skin should be sharp. (3) Twelve days are not too long to leave the arm and face in contact. (4) It is neither necessary nor desirable to cover the site of operation with plaster-of-paris; on the contrary, the plaster bandages should be so applied as to leave it freely accessible, and the dressings should be changed occasionally. (5) The stronger sutures should be of silkworm gut. (6) Care should be taken not to leave a fragment of mole behind. Cutting the flaps free is a difficult step in the operation, as they have to be cut where folded, and it is in some cases difficult to get a good view. A very sharp knife should be used, and a strong light should be thrown into the hollow. At the same time the skin should be carefully swabbed free from blood. (7) It should be made absolutely sure that both flaps are *entirely* cut through before the arm is allowed to move an inch away from the face. (8) The strapping used should be old-fashioned diachylon, and not the irritating plasters often sold on rollers. (9) The iodoform gauze should be well rinsed out in warm sublimate solution, 1 in 2,000. (10) No drain of any kind should be inserted between the flap and its bed; it is not necessary, and may be mischievous.

Lodgment of a Foreign Body in the Air Passages for Seventy-two Days.—The patient of R. A. Wilson was a man of forty-five years, who, while intoxicated, met with the accident referred to in the title of the article. The next morning he presented the following symptoms: Great pain over the lower posterior portion of the right lung, dyspnœa, and severe paroxysmal cough, with the expectoration of much frothy muco-purulent sputum streaked with blood. No bony crepitus could be elicited. His temperature was 100° F., his pulse rate was 84, and his respirations were 24 per minute. There was dulness on percussion over the infrascapular region on the right side, and the vocal fremitus was much increased over this portion of the lung. Loud whistling, breathing, accompanied by snoring and silibant râles, together with great intensification of the vocal resonance, was heard over the same area. After a week in bed he resumed work, though continuing to have paroxysms of cough and dyspnœa, in one of which he expectorated the proximal portion of a vulcanite pipe stem half an inch long by one-third of an inch broad, which he then recognized as belonging to the pipe he had in his mouth at the time of the accident. A few days after the event the signs above noted disappeared, and the cough and dyspnœa no longer troubled the patient. The noteworthy features of the case are: (1) The patient's unconsciousness of having swallowed the foreign body; (2) the length of time that it remained undiscovered; and (3) the physical signs. When a foreign body becomes impacted in a bronchial ramification, one would naturally expect to find collapse of the portion of lung supplied by it. The pipestem, however, was peculiar in that, although acting as a plug, it also probably allowed air to enter through its perforation; and it is uncertain whether the signs of consolidation were true and were caused by the presence of the foreign body, or whether the signs were false and were produced by the vulcanite acting as a resonator.

British Medical Journal, November 22, 1902.

Psoriasis Inherited (?) from a Myxœdematous Parent.—Evelyn A. W. English was recently consulted by a young woman, aged twenty-seven years, who had been suffering from a persistent attack of psoriasis for the last four years. No treatment had proved of any benefit. Vapor baths were tried with some improvement, but when the writer learned of the myxœdema of the mother, thyroid extract was ordered. Recovery from this time was rapid, and in less than a fortnight the psoriasis had disappeared. The general health was good, and there was no other evidence of thyroid deficiency.

Treatment of Rheumatoid Arthritis.—W. J. Midelton calls attention to this case of rheumatoid arthritis, which occurred in a woman of forty-three years. She was treated by blisters and massage. The blisters were first applied one on each side of the tenth dorsal vertebra, and were kept open with savin ointment about twelve days. About a month later others were applied, one on each side of the lower cervical and upper dorsal vertebræ. The patient improved so much that she could do house work. She had been bedridden. The writer states that this treatment is based on what he believes to be the true pathology of the disease—the neural theory, others urging the infective theory. He sees no reason why the two should not go hand in hand. He thinks if this disease were called poliomyelitis many misconceptions of its true nature would be to a large extent removed.

Case of Complete Paraplegia Successfully Treated by Forcible Extension of the Spine.—T. Outterson Wood and James Cantlie report this case. The patient was a boy of ten years. On his admission to the hospital he was found to be suffering from complete paralysis of both lower extremities. This had lasted for about six months. There was marked rigidity and a good deal of adductor spasm, but there was no flexion of the knees or thighs. The knee-jerks were greatly exaggerated, and there was ankle and pattellar clonus. The plantar reflex was increased and Babinski's sign was markedly present. The patient was kept on his back for three months and passive extension was applied to the lower extremities by means of pulleys and weights, the shoulders being fixed at the same time the legs were massaged daily. At the end of three months the spine was forcibly extended under an anæsthetic and a Sayre jacket applied, while the extension was kept up by means of the pulleys. All the night following the operation the child complained of great pain in the knee-joints, and the extension was discontinued. The patient was still kept on his back in the jacket. When it was taken off, he could move both legs. Sensibility to pain had also increased. He was kept on his back for some months, and then he began to attempt to walk. He has improved steadily ever since, until now he can run and jump. The other disturbances have almost entirely cleared up.

Case of Motor Aphasia, with Hemianæsthesia, but No Hemiplegia.—William B. Bennett describes this case, which presents four prominent features: Motor aphasia, right-sided hemianæsthesia, no hemiplegia, and paralysis of the tongue on the right side. As to localization of the lesion the writer says that hemianæsthesia may be caused by a lesion in any one of the following situations: (a) The posterior third of the hind limb of the internal capsule, where the different fibers of general sensation ascend to the brain. Such a lesion without any hemiplegia is extremely rare, and when present is usually accompanied by at least partial paralysis of the leg, also by hemianopsia, disturbance of hearing, and sometimes of taste and smell, none of which were present. (b) The cortex. This would of necessity be an extensive lesion, and would involve the motor areas, causing considerable paralysis and probably twitchings. (c) The subcortical area. That is somewhere in the white matter which lies between the cortex and the internal capsule (corona radiata), and this the writer considers the most likely position. Applying the same tests to the motor aphasia, the same conclusion is reached; for if the lesion had been in (a) the internal capsule, it must have been at the anterior end of the hind limb, at the genu, since it is here that the fibers to the tongue and those concerned in motor aphasia pass through. (b) The cortical center concerned in motor aphasia is at the posterior end of the third left frontal convolution, but this is unlikely from the absence of paralysis or twitchings. Thus we are compelled to fall back upon the subcortical area as the most likely position for the lesion; and this would also account for the very slight weakness down the right side. The writer believes that the lesion in this case was a softening in the subcortical area of the brain.

Deutsche medicinische Wochenschrift, November 6, 1902.

Enlarged Thymus and Sudden Death.—M. Penkert reports two cases which show that the thymus gland, if sufficiently enlarged, may cause marked pressure upon the upper air passages, and thus give rise to sudden death through strangulation. The first case was a new-born child who lived only three hours after birth. The respirations were bad from the moment of birth, and artificial respiration was attended with but little result. Upon autopsy the child was found to be normal in all respects except in the possession of a very large thymus gland. This gland was 5 cm. long, from 2 to 6 cm. broad in different portions, and 1½ to 2 cm. thick. The second patient was six months of age, and had never been sick up to the time of the fatal attack. This was a sudden development of dyspnœa, which speedily resulted in death. Upon autopsy nothing abnormal except an enlarged thymus was found. This consisted of two lobes, the right being 10 and the left 8½ cm. in length. Small hemorrhages were present throughout its substance.

Berliner klinische Wochenschrift, November 10, 1902.

Meningococcus Septicæmia.—H. Salomon reports a case of septicæmia in which Weichselbaum's meningococcus intracellularis was twice cultivated from the blood in pure culture. Only two endeavors to thus obtain this organism were made, one upon the fourth and the other upon the twenty-seventh clinical day. Both were successful. Lumbar puncture was also tried, and the above organism demonstrated therein; this fluid, however, was not cultivated. Clinically, the case was characterized by an irregular fever, and the other familiar constitutional symptoms of general septicæmia. A macular eruption was present which was more or less varying in character and transient in appearance. The entire course of the case covered about five months, during which many remissions and exacerbations took place. Recovery ensued.

Munchener medicinische Wochenschrift, November 11, 1902.

Croupous Pneumonia and Sepsis Due to the Pneumobacillus of Friedlander.—E. Phillipi reports a fatal case of lobar pneumonia in which Friedlander's bacillus was cultivated from the blood during life, and was obtained from the pulmonary lesions at autopsy. In the latter lesions other microorganisms were present, but the pneumococcus of Fraenkel was not found. This shows that the latter organism is not the sole producer of typical lobar pneumonia in man.

Cerebrospinal Meningitis and Purulent Rhinogenous Meningitis.—Theodor Struppler reports three cases which show that a cerebrospinal meningitis may have its origin in a chronic purulent process located in the antrum of Highmore. In all of the cases such a chronic process had been in existence for some time when cerebrospinal meningitis suddenly developed and proved rapidly fatal. Lumbar puncture was practised in all cases, but was negative. Upon autopsy the characteristic lesions of cerebrospinal meningitis were found, together with the evidences of the chronic process above mentioned.

Value of Cryoscopy in the Diagnosis of Death by Drowning.—Revenstorf, by experimental work upon rabbits, has endeavored to ascertain whether an estimation of the freezing point of the blood taken from the right and left sides of the heart respectively is of any value in the diagnosis of death by drowning. The supposed value of the method is based upon the fact that in drowning a certain portion of the drowning fluid finds its way into the pulmonary capillaries, and from thence into the left side of the heart, so that the blood there contained would be of less molecular concentration, and have a higher freezing point than that on the right side of the heart. Revenstorf finds that in many cases of death by drowning the freezing point of the blood in the left side of the heart is much higher than that in the right side, the difference being from ten to twenty-seven degrees. In many other cases, however, no such difference can be demonstrated, so that this sign is only of value when the freezing point of the blood in the left heart is quite perceptibly below the *normal*, thus showing that the blood in that location has been diluted by water absorbed from the lungs.

French and Italian Journals.

Surgical Treatment of Appendicitis.—Moty depends upon the state of the pulse in doubtful cases. When it beats 100 times to a minute, he discusses the urgency of operative interference, and does not hesitate in this course if, from hour to hour, the pulse-rate increases. If, on the contrary, after several examinations, he does not find any change in the number of beats, he waits, ready to operate in case of acceleration.—*Journal des Praticiens*, November 8, 1902.

Hypertrophy of the Prostate and Perineal Prostatectomy.—Loumeau reports two cases of hypertrophied prostate operated on by Albarran's method of total perineal prostatectomy. They were perfectly relieved of numerous urinary disorders; the cure in one case now being of seven and one-half months' duration, and the other of five months. The first patient had suffered from retention for four years, with acute crises, particularly painful for the last two months. He can now empty the bladder entirely without a catheter. The second patient, who for twenty-seven months suffered from complete chronic retention, has been relieved in the same manner from all of these disturbances.—*La Médecine Moderne*, November 5, 1902.

Experimental Researches and Anatomico-Pathological Observations in Regard to Segmenting Myocarditis.—Giuseppe Giacomelli concludes that fragmentation and disintegration of the myocardium are the lesions most frequently met with in autointoxications, in acute poisoning, and in poisoning by chloroform, mercury, fungi, etc. The rapid contractions of the heart produced by electricity do not cause segmentation, neither do the brusque contractions of the heart produced in animals by faradization preceded by experimental intoxication. Fragmentation and disintegration of the myocardium are of more serious import than fatty degeneration. There is no relation between general degeneration of the fibers and segmentation.—*La Riforma Medica*, November 3, 4, and 5, 1902.

Pericardial Hæmatoma from Rupture of a Branch of the Right Coronary Artery.—M. J. Delépine presents this case. The patient was a man of sixty-six years, suffering from the sequelæ of an attack of grip—anorexia, constipation, and asthenia. The objective examination was almost completely negative. A saline purgative was ordered, and it was thought that rest, combined with tonics, would restore the patient again to health. Two days after his entrance to the hospital, in getting out of bed, he fell, and died in a few minutes. At the autopsy the pericardium looked like a distended sac, bluish in color. On incising it, there escaped a rush of blood with clots, the whole weighing about 250 to 300 grams. The internal surface of the pericardium was normal, showing not a trace of hemorrhagic pericarditis. The heart was carefully examined. There was neither thrombosis nor rupture of the main branches of the right coronary artery. The hæmatoma seemed to have been caused by the rupture in a small artery, which sprang from the bifurcation of the two branches of the right coronary artery. This tiny branch showed fatty degeneration.—*Journal des Sciences Médicales de Lille*, November 8, 1902.

Filaria Medinensis.—Nicola Cantàfora says that the usual method of treating this disease is to exert gentle traction of the worm, being careful not to injure it in any way and trusting to its gradual exit from the skin. In a case which he recently had to treat, he cut the parasite with the scissors, allowed the milky thick fluid which it contained (masses of embryos) to flow out, and then injected within the parasite about a quarter of a Pravatz syringeful of a 3-per-cent. solution of carbolic acid. Several other injections were then made around the cutaneous lesion. The parasite was then tied at its cut end with a piece of silk and placed as usual around a little rod. Two days later, about 10 cms. of the filaria came out spontaneously, and by gentle traction 12 more were easily extracted. Another recision of the parasite was performed with subsequent injection of carbolic acid, and two days later the whole worm came out. Recovery was complete. The author is aware that one case alone is not convincing, but suggests that this method, having been so successful, be given further trial.—*Giornale Medico del Regio Esercito*, October 31, 1902.

Annals of Surgery, October, 1902.

Acute Suppurative Pancreatitis.—F. W. Murray reports the case of a man, aged fory-one years, alcoholic, and with a history of a series of supposed bilious attacks. When seen by the author he was vomiting and had severe epigastric pain. The abdomen was distended with marked prominence in the left epigastric region, which contained a mass about as large as a cocoanut, tense, well-defined, and tender, giving dulness on percussion. A diagnosis was made of acute suppurative pancreatitis. Through an incision in the left rectus muscle, some twenty ounces of a brownish seropurulent fluid escaped, and the swollen pancreas could be felt lying at the back of a large cavity. This was cleansed and irrigated. The discharge from the opening continued for some weeks, but the patient gradually improved, and was discharged from hospital in a little over four months with his wound completely healed. Eight months later he was reported as having gained sixty-five pounds and as being well in every respect.

A Case of Trigger Fingers.—F. Griffith reports the case of a Polish woman, aged fifty-seven years, who suffered from a sudden locking of the knuckle-joints of the left second and third fingers. The affection had lasted fifteen years. The cause could not be ascertained. The condition was manifested in movements both of flexion and extension. Upon attempting to grasp an object, as, for example, a chair-back, with the left hand, the thumb, index, and little fingers clasped naturally, but the ring and middle fingers, after describing about one-third of the arc of flexion, suddenly became locked at their metacarpophalangeal joints, and the woman was utterly unable to accomplish further movements of those fingers unaided. She had, by long practice, established a complementary action of her other hand, when, by pushing the affected fingers beyond the lock, an apparent dislodgement took place almost audibly, and the woman was then able to hold the object or to clinch her hand. Movements of extension were carried out in a similar but reversed manner. Opening through the first third of the arc was entirely voluntary; during progress through the middle third absolute fixation took place; aided by the other hand, release with a jerk was obtained, followed by full and easy straightening.

Results of Operations on the Kidney for Tuberculosis.—E. Garceau presents the following conclusions: (1) Tuberculosis is rarely, if ever, primary in the kidney, and the original focus is in some other organ in more direct contact with the external air in the majority of cases. (2) The presence of a primary focus of disease in the body, even if the disease has been thoroughly eradicated from the urinary tract, makes the ultimate prognosis in these cases doubtful at least. (3) Such foci may remain permanently quiescent, but they may also become excited to activity by a generally low condition of the system, or by causes unknown to us. (4) Patients should be told of the danger as regards the future for them, and they should lead lives of the greatest regularity, with strict attention to hygiene. A change of climate is very beneficial in these cases. (5) Reported cures of long duration occur, but they have been few. (6) Nephroureterectomy should be done in all cases in which the ureter is diseased and the patient's condition allows of it. The bladder should be subsequently treated if diseased. (7) An abandoned tuberculous ureter is an especial source of danger on account of the great liability of subsequent tuberculosis. (8) Nephrotomy alone should be rejected except as a preliminary to a later nephrectomy. (9) Resection is not justifiable, for we can never be sure that the portion removed is the only portion diseased.

Total Excision of the Scapula with Preservation of the Upper Extremity.—The patient of S. P. Delaup was a negro twenty years of age. Without apparent cause he began to have stiffness in the movements of the right arm with a moderate swelling of the shoulder. Examination at the time the patient was seen revealed a suppurating at the sinus at the back of the junction of the spine with the spinal border of the scapula. Under anæsthesia the sinus was laid open and conjoined caries and necrosis of the scapula were found, and so extensive that excision of the whole bone was called for. The author describes the technical steps of the operation, and congratulates himself upon the successful functional recovery obtained. The patient can lift readily any moderately heavy article. He can place his hand on either ear or shoulder, on the back of the neck, and can pass his hand over the whole of his forehead and face and behind his back. He can bring his hand to sweep over the whole face and cheek. There is a considerable amount of hard, fibrous material about the new joint, and, as a result of this rigid condition of the parts, the upper extremity of the humerus, itself involved in the mass, is held much more firmly in position than would otherwise be the case, assuring the stability of the humerus. Two excellent pictures illustrate the anterior and posterior aspects of the joint after operation.

Gunshot Wound of the Thorax Involving the Heart.—L. J. Hammond was called to see a man of fifty-one years of age, who had been accidentally shot in the chest, the wound of entrance being one and one-half inches above the ensiform cartilage, and about the same distance to the left of the sternum. A large hemorrhage extended from the nipple line of the posterior axillary line and from axilla to diaphragm. The patient did well for nearly three weeks, when he was suddenly attacked with vomiting, and died almost instantly. Autopsy revealed the following conditions: At the wound of entrance the bullet had fractured the rib at that point, passing through the pericardium and through the apex of the heart, making a wound about one-quarter of an inch in depth. It then passed through the pleura and gained exit from the thorax between the sixth and seventh intercostal space, being found in the subcutaneous tissues, after having passed through all the deeper tissues of the back. Its presence could not be early detected on palpation because of the presence of the immense hæmatoma, and later because of its being embedded in organized blood-clot. The entire heart muscle was enveloped within a well-organized blood-clot, and about a gallon of serum and blood was removed from the pericardium and pleural cavities. All the other organs were apparently normal. The peculiar feature of the case is the absence, after recovery of shock from the wound, of any cardinal symptoms of wound of the heart.

Excision of the Lumbar Lymphatic Nodes and the Spermatic Vein in Malignant Disease of the Testicle.—J. B. Roberts says that if the exact nature of the pathological process is known, it may be sufficient to excise the nodes and leave the vein untouched in carcinoma, or to resect the vein and leave the nodes untouched in sarcoma. If the nature of the process is unknown, it is better to operate on both nodes and vein. The operation is thus described: The abdominal incision should be median and extend about two inches above and about two inches below the navel. The small intestines should be pushed to the right side of the patient, and the posterior layer of the peritoneum opened over the aortic bifurcation. Care must be taken to avoid injuring the inferior mesenteric artery, alongside of which will be seen lymph nodes. These nodes are not to be disturbed, because they receive lymph from the intestines and not from the testicles. The nodes to be excised lie upon and at the sides of the aorta from its bifurcation up to the level of the renal vein. They vary in size, being often not larger than a grain of wheat, and may be embedded in fatty tissue. The safest course, probably, is to remove all the adipose tissue found in front of the aorta and cava and at the sides of these great blood vessels. It is, perhaps, wise to excise the glands on both sides of the median line, though only one testicle be diseased. Resection of the spermatic vein should be restricted to the side corresponding to that of the malignant tumor. One illustrative clinical case is narrated.

Fatal Acetonæmia Following an Operation for Acute Appendicitis.—The patient of G. E. Brewer was a school boy of twelve years. A perforated gangrenous appendix was found in a small abscess cavity containing two drachms of foul pus. Duration of anæsthesia was twenty-five minutes. On the third night after operation he suddenly awoke and began to scream. These attacks were renewed at intervals during the next day. The wound conditions appeared normal, and there was no evidence of cranial nerve palsy or irritation. No cause for the peculiar mental condition could be discovered, but a peculiar sweetish, ethereal odor of the breath was noticed, and a diagnosis was made of acute autointoxication from the presence of acetone and diacetic acid in the blood. This conjecture was confirmed by finding large quantities of both substances in the blood and urine. Free catharsis, diuresis, and intravenous injections of chemically pure sodium bicarbonate were instituted, but the patient died about twenty-four hours later. In the final hours the mental symptoms assumed more of a passive type. Brewer has never known of a similar case. Possible causes are trauma, sepsis, drug action, and autointoxication (ptomains, uræmia, and acetonæmia). As regards the possible relation of anæsthesia to the condition, Brewer notes the presence in the urine of a pathological amount of acetone in seven out of thirty-three cases following anæsthesia, the records being taken from his hospital service. In five of these chloroform had been used, and in two ether. None of the cases were diabetic, and in none was there a reaction for acetone before the administration of the anæsthetic. In all the acetone appeared on the day following the operation. In two it was found on the second and third days, in the remaining five on the second. In six of the cases there were no symptoms which could be attributed to acidosis; in the seventh death occurred thirty-six hours after a gastroenterostomy for carcinoma, with rather indefinite symptoms of so-called secondary shock.

University of Pennsylvania Medical Bulletin, Nov., 1902.

Thrombi Composed of Agglutinated Red Blood Corpuscles.—Simeon Flexner concludes that the agglutination of red corpuscles *intra vitam* is not uncommon in infectious diseases in man and animals. A special variety of thrombi is produced through this agglutination, which may be denominated agglutinative thrombi. When such thrombi are old, or when the agglutination is compact, they may present appearances to which the name of "hyaline thrombi" has been applied. Other alterations of the blood than those arising in infectious diseases may bring about agglutinative thrombosis, the nature of this alteration being little understood. Poisons which destroy corpuscles rapidly are provocative of agglutinative thrombosis. The so-called "fibrin fermen thrombi" are probably nothing else than agglutinative thrombi.

Vaccination and Serum Therapy against the Bacillus of Dysentery.—Frederick P. Gay concludes that the bacillus of dysentery (Shiga's) is the cause of acute and other forms of dysentery in tropical and temperate climates, and, probably, of a part of the summer diarrhœas prevailing in warm countries among infants. The bacillus of dysentery, cultivated outside of the human body, quickly suffers a reduction in virulence for guinea-pigs, but the virulence can readily be increased by successive passages through the bodies of these animals. The passage of B. dysenteriæ through guinea-pigs permits of the establishment of a uniform grade or degree of virulence in the organism, irrespective of its sources, which adapts it for the production of vaccines of quite uniform activity. From experiments made with these vaccines the author judges that a useful serum therapy of bacillary dysentery and of certain forms of the summer diarrhœas of infants is rendered highly promising.

Study of the Bacteriolytic Serum-Complements in Disease.—Warfield T. Longcope says that normal individuals show slight fluctuations in the bacteriolytic complement-content of their blood. In many prolonged chronic affections, such as nephritis, cirrhosis of the liver, and diabetes mellitus, there is a marked decrease in the bacteriolytic blood complement, which becomes more marked toward the end of the disease. Terminal infection in chronic disease is probably the direct result of the diminished state of the bacteriolytic complement. The blood serum of certain individuals suffering from chronic [illegible] not show a [illegible]. These individuals appear to escape t[illegible]. [illegible] leucocytosis is frequently associated with [illegible] complement-content of the blood serum for typhoid and [illegible] bacilli. The blood serum of some typhoid fever [illegible] shows a diminution in the specific complement for the typhoid bacillus. Human blood serum contains a multiplicity of bacteriolytic complements.

Bubonic Plague.—Simon Flexner considers the [illegible], mode of spread, and clinical manifestations of bubonic plague, and states that in spite of all efforts, it has invaded the Western Continent. A stupendous progress has characterized the study of the present epidemic. The discovery of the bacillus of plague has centered attention upon the one agent of propagation; the study of the life history of the germ has eliminated the indefinite agents of conveyance included in air, soil, and water and substituted tangible means of dissemination. This knowledge is bearing fruit already, as observed in the beneficial effects of evacuation of villages and quarters with thorough disinfection or destruction of premises. Inoculation with Haffkine's anti-plague remedy, according to the conclusions reached by the Indian Commission, is found to diminish the incidence of plague attacks, and diminishes the death rate. It does not appear to confer any great degree of protection within the first few days, but the protection lasts for some weeks, possibly for a number of months.

A Study of Immunization Hæmolysins, Agglutinins, Precipitins, and Coagulins in Cold-Blooded Animals.—Hideyo Noguchi concludes from his researches that (1) Artificial hæmolysins, agglutinins, antiagglutinins, serum precipitins, aqueous humor precipitins, and milk coagulins can be produced through immunization in certain cold-blooded animals. (2) The hæmolysins and agglutinins for erythrocytes can be produced in animals which do not possess erythrocytes. (3) Iso-agglutins and iso-hæmolysins can be produced in certain species of turtles. The iso-bodies thus developed have a slight erythrolytic action upon the blood of other, though related, species of turtle. (4) The complements of turtle's blood are rendered inactive by a temperature of 50° C., maintained for thirty minutes. (5) The precipitins and coagulins for aqueous humor and milk, respectively, can be produced in animals which do not possess the corresponding fluids in the strict sense. (6) The above facts demonstrate the widespread distribution of common receptors through the animal kingdom and extend the chief tenets of Ehrlich's hypothesis to invertebrates and vertebrates among the cold-blooded animals.

Leptothrix Infection in Animals.—Richard Mills Pearce says that the confusion which exists concerning the filiform organism which is the subject of his article is shown by the fact that although it has been the subject of [illegible] five original communications, it is referred to in the literature of bacteriology under eleven different names. The painstaking investigations of Flexner, which were confirmed by Muscatello so describe the organism, its morphology, and the character of the lesions that no doubt of its identity with the Streptothrix cuniculi remains. The variations of cultures led Flexner to classify it as a new species. The difficulty, however, is not so much one of variation in the results of cultivation as it is one of lack of uniformity in the methods of cultivation. Until some one with fresh material at hand suggests anew a comparative study, it seems advisable to consider all the forms described to be identical. The establishment of such identity would lead to a change in nomenclature. The term streptothrix must be dropped, for in the [illegible] of seven different investigators true branching has not been discovered. The author considers that the adoption of the cognomen leptothrix necrophorus is imperative.

Recurrent Vomiting in Children.—Henry [illegible] Shaw reports four cases of the disorder which is characterized by a sudden onset of persistent vomiting without other gastrointestinal symptoms. Some authors believe that it is only one of the manifestations of the uric-acid diathesis. In the cases reported there was a marked neurotic or gouty tendency inherited from [illegible] both parents. The vomiting is the chief and often the only symptom and may be mild or severe. It may occur with or without provocation. Thirst is constant, but there is no desire for food. The disease lasts from [illegible] hours to eight days. Recovery is almost instantaneous. The disorder is apt to recur, but without regularity. Prognosis is favorable, but treatment is unsatisfactory. The indications are to give the stomach absolute rest and to get the bowels to act. Marfan found that large rectal injections of normal salt solution twice a day [illegible] the best results.—*Archives of Pediatrics.*

Society Reports.

THE PRACTITIONERS' SOCIETY.

173d Regular Meeting, Held on Friday, October 10, 1902.

George L. Peabody, M.D., President pro tem.

Operations upon the Uterine Appendages for Sterility.—Dr. W. M. Polk read this paper (see page 881).

Dr J. W. Brannan said that about two years ago he received a letter from a well-known New York surgeon stating that he had devised an operation for the transplantation of sound ovaries into women who had lost their ovaries, and asking Dr. Brannan whether he had any patient who would submit to the operation for the sake of having children. This surgeon subsequently informed Dr. Brannan that he had sent a similar letter to thirty physicians, and among their combined clientele not a single sterile woman was found who wished to have this function restored.

Dr. T. Mitchell Prudden, in reply to a question, said that at an operation upon the ovaries in which the operator was confronted with alterations so slight or so obscure that he was in doubt as to his further procedure, the frozen-section methods of rapid microscopic diagnosis were not likely, in his opinion, to be very helpful. The reason of this was that these methods were not sufficiently delicate to permit of such accurate differentiation of tissues as would under these conditions alone be helpful.

Rupture of the Retina and Choroid.—Dr. Charles Stedman Bull reported this case. The patient was a man, who, while riding in the Central Park last March, was thrown from his horse, striking on his head. He was picked up unconscious and taken to the Presbyterian Hospital. There was bleeding from the left ear, and it was supposed that he had sustained a fracture of the base of the skull. There was a scalp wound about the middle of the left parietal bone, but no fracture of the vault could be discovered. The left pupil was contracted.

After thirty-six hours the man regained consciousness, and his condition gradually became normal, but two or three days later he stated that he could not see with his right eye. An examination showed that the right vitreous body was filled with blood. This condition gradually cleared up, disclosing a rupture of the retina and choroid, leaving the white sclera showing through. The retraction of the ruptured parts have left a gap of considerable size in the fundus, reaching to the optic nerve. The patient has no central vision whatever, but that from the eccentric portion of the retina has come up so remarkably that he can now read diamond type with the affected eye. The left eye was normal and has remained so.

With the exception of a rather extensive subconjunctival hemorrhage on both sides, Dr. Bull said this patient showed no further evidences of a fracture of the base of the skull The rupture of the drum membrane of the left ear, which occurred at the time of the accident, has healed; his hearing on that side is now practically restored, and he has no subjective symptoms referred to the ear.

Dr. George F. Peabody said he had seen two cases of what he believed to be fracture of the base of the skull in which the middle ear was filled with blood, but in which there was no rupture of the drum membrane. Both cases ultimately recovered, after having suffered from delirium.

A Case of Paralysis with Unusual Symptoms.—Dr. Brannan said that two weeks ago he was called to see a woman who was at first supposed by her husband to have a hysterical attack. He found her almost unconscious, with loss of the power of speech and almost completely paralyzed on the right side of the body. This led him to believe that he had to deal with a case of hemorrhage or embolism on the left side of the brain, involving the speech center. Later in the day, the left side of her face became paralyzed, and the power of speech returned to some extent. On the following day she was unable to move her eyes to either the right or the left; she could raise them slightly, but was unable to close her left eye. Since then she had gradually recovered the use of her right arm and leg—the arm recovering its power first, which was unusual—but there was still some incoordination. The paralysis of the left side of the face and that of her eyes continued; the latter seemed to be equally affected. Sensation on the right side, including the face, was impaired, while the opposite (paralyzed) side of the face was hypersensitive. The pupils were about medium in size, and reacted to light equally. The hearing was much dulled and there was considerable difficulty of articulation.

This patient, Dr. Brannan said, was forty-six years old, and gave an indefinite history of some recent menstrual trouble. The heart was apparently normal. The urine at first contained considerable albumin, but since then it had cleared up, and was now normal.

Dr. Brannan said that while he was uncertain as to the nature of the lesion in this case, he thought that it was located in the lower portion of the pons, involving the nuclei or roots of the third, fifth, sixth, seventh, eighth and ninth nerves. The pyramidal tracts were evidently affected in the beginning of the attack, recovering later. Thrombosis of the basilar artery with consequent softening of the pons seems the most probable lesion.

Ascending Spinal Paralysis.—Dr. Andrew H. Smith reported this case, which he saw in consultation at the Long Branch Hospital. The patient was a man who was injured while diving in shallow water. He was taken to the hospital, and found to be completely paraplegic below the waist. Nothing could be made out in the way of a lesion of the spinal column, but there was an absence of sensation and motion of the lower part of the body. The paralysis gradually ascended, involving the intercostal muscles, respiration being carried on entirely through the movements of the diaphragm. Death occurred forty-eight hours after the accident, and was due to the accumulation of secretion in the lungs, which could not be expelled on account of the paralysis of the intercostal muscles.

Dr. Smith also mentioned another case in which this ascending paralysis of the spinal cord was very well illustrated. The lower part of the body was first involved; the paralysis gradually crept up, affecting the lower intercostal muscles, then the upper, while the diaphragmatic breathing continued until death occurred from the collection of secretion in the lungs, coughing being impossible by the action of the diaphragm alone.

A Case of Spontaneous Subarachnoid Spinal Hemorrhage in a Bleeder.—Reported by Dr. Edward G. Janeway. The patient was a young man, who, while apparently recovering from a slight attack of grippe, fell to the floor, and upon examination it was found that there was a complete loss of power and sensation of the legs and lower portion of the body. The onset and character of the symptoms, a rigidity of limbs occurring on bending the body, led to the probable diagnosis of spinal hemorrhage in a hæmophilic. The fact was elicited that the patient's brother was a bleeder, and had lost the sight of one eye from a retinal hemorrhage.

The patient died at the end of two weeks from gradual ascending paralysis. An autopsy showed a hemorrhage filling the subarachnoid space, and extending up to the middle cervical region. There was also some blood between the dura and arachnoid, due to small rupture in arachnoid membrane over cauda equina.

If this patient had not been a bleeder, Dr. Janeway said, an operation would have been advised. The speaker said he had never seen nor heard of a similar case.

A Case of Acute Ascending Paralysis, with Recovery.—Reported by Dr. W. M. Polk. The patient was a woman, about fifty years old, who, during the course of the menopause, began to suffer from an acute ascending paralysis, which gradually involved the entire body as high up as the chin, respiration being continued by means of the diaphragm. She remained in this condition for about a week, and then gradually made a complete recovery, and has apparently remained well up to the present time. During her illness she was carefully examined by several neurologists, who failed to find any evidences of hysteria or simulation. Her treatment consisted of enormous doses of potassium iodide. There was no distinct evidence of syphilis, but there were some grounds for believing that she had not been entirely proper in her method of living.

Minute Sarcoma Involving the Sixth Nerve.—Dr. Janeway reported the case of a man who developed a paralysis of the sixth nerve. He was operated on for strabismus and died within a week after the operation. The autopsy showed a sarcoma, about half the size of a pea, which sprang from the dura under the pons, pressed on the sixth nerve and pons at this site, subsequent acute softening of the pons had produced the fatal result. The ophthalmologist was severely blamed by the patient's family for operating on the strabismus, attributing the fatal result to the operation.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held November 17, 1902.

Alexander Lambert, M.D., President.

A New Trachoma Forceps.—Dr. H Davison Saril presented this instrument, which he had recently devised for the expression of the lymphoid bodies in trachoma. He claimed that it would grasp any portion of the conjunctiva without slipping, and would remove the lymphoid matter with the least traction and the least trauma.

Unscientific and Careless Prescribing; Secret and Proprietary Remedies.—Dr. Harry R. Purdy presented a paper with this title. He said that he had been astonished to see the apparent lack of knowledge of incompatibles in prescriptions by men who are very capable and well-informed in other respects. Various examples of prescriptions illustrating this were given. Emphasis was laid upon the fact that corrosive sublimate was incompatible with almost everything, yet was often prescribed in tablet form along with various other drugs. The author condemned the practice of using ready-made and often stale, insoluble and inert medicines. In certain quarters, said the speaker, it seemed to be the fashion to decry all drugs, and to pose as if as much afraid of them as the whilom drunkard is of liquor. But more to be condemned even than these physicians were those who prescribed patent medicines. By doing so these practitioners not only confessed that they were incompetent, but violated the code of ethics. The author said that the difference between a proprietary and a patent medicine was more apparent than real. A definition of a patent medicine, which seemed to him very good, was, "a medicine the formula of which is printed on the label, but which formula does not give a true indication of what the remedy contains." The principal reason for the present state of affairs, Dr. Purdy believed, was that graduates of medicine were not taught either pharmacy or pharmacology.

Dr. E. Eliot Harris said he had been particularly struck by the author's assertion that there was very little distinction between a patent medicine and a proprietary medicine. To his mind the latter was the generic term, and the designation patent medicine a specific one. At the present time, in order to secure a patent on a medicine, it was necessary to file at the capital not only the formula but the working formula—that is, one which a competent pharmaceutical chemist could use for the reproduction of the article in question. The patent medicine, therefore, was a perfectly ethical medicine, and gave the medical practitioner all that he needed to know with regard to the medicine. Old-time patent medicines were very different, and this fact should be borne in mind when criticizing them. The manufacturers of certain proprietary medicines were willing to give to the profession their ingredients, but would not divulge the exact mode of manufacture.

Dr. Frederick Holme Wiggin said he coincided fully with the views expressed by the last speaker. The committee on publication of the New York State Medical Association had endeavored to bring the advertising columns of their publications up to the proper standard, and the success or failure of such efforts must depend upon the medical profession. With regard to the use of tablets and the giving of medicines by physicians in their offices to their patients, the speaker said he had adopted this plan for a long time and felt that it was a good one. All physicians knew that patients were in the habit of having prescriptions filled over and over again, even when the physician distinctly intended its use should be limited to a short time. By office dispensing the physician controlled this important part of his work. Such patients do not come back for medicine, but for the physician's advice. Nor could he agree with Dr. Purdy that a great many of our medicines did not preserve their potency well when put up in tablet form.

Dr. George D. Stewart said that Dr. Purdy had presented a good sermon, yet he was not one of those who believed the profession was going backward. On the other hand, he firmly believed that the profession was going forward, at times almost too fast. Such papers as the one now under discussion were, therefore, most important by causing us to pause and think. He would personally plead guilty to a number of counts in the indictment presented in this paper. He agreed with the author that the usual method of office dispensing was wholly unscientific and undignified. It was certainly undignified and unscientific to have to look over a price-list to find out the ingredients of various tablets. It would be a good step if the medical colleges would introduce a proper course in pharmacology. The older graduates would find it the part of prudence, at least, to prescribe very few drugs, and to know those drugs very thoroughly, and as for the matter of incompatibility, this could be largely avoided by prescribing simples.

A Complete Change in Prescription Writing in the Last Decade.—Mr. Thomas J. Keenan spoke from the standpoint of the pharmacist. He said that pharmacists viewed with alarm the growing tendency among physicians to prescribe proprietary articles. A comparison of the prescriptions written in the last decade with those of the decade immediately preceding showed a complete change in the mode of prescription writing. Taking fifty prescriptions at random from a drug store doing a family prescription business, it was found that, whereas in 1882 out of fifty such prescriptions forty-eight were for official preparations, in 1901 forty-one out of the fifty prescriptions were for proprietary articles. While the standard of pharmaceutical education was being raised from year to year it must be said that the medical profession had not always shown a corresponding disposition to recognize the professional status of the pharmacist. The pharmacist of the present day groaned under the burden of dead stock of synthetic drugs made in Germany and having a very ephemeral popularity.

Dr. James J. Walsh cited examples of the folly and danger of informal prescribing—the giving of advice to the laity by physicians when they are, so to speak, off duty, or on a vacation. A case of belladonna poisoning was referred to which had been caused by a lady taking "rhinitis tablets," because she had learned of the name of this remedy through a physician who had prescribed it for her. A strong moral impression was produced by the physician's writing or having printed on his prescription blanks a warning against the refilling of the prescription without his knowledge and consent.

Dr. Emil Mayer said he doubted very much whether any pharmacist of to-day made his own fluid extracts and elixirs, and whether the pharmacists were not themselves largely responsible for the present attitude of the medical profession in regard to prescribing. He thought we should distinguish between elegant pharmaceutical preparations, made and marketed on ethical lines, and those which are simply made for gain. Not infrequently physicians and their patients had been annoyed by the wholly uncalled for and illegitimate criticisms made by pharmacists on certain prescriptions. The speaker indorsed the position taken by Drs. Harris and Wiggin with regard to the differentiation between proprietary and patent medicines, and the lines which should be drawn around ethical advertisements.

Dr. EDEN V. DELPHEY said that he had secured the aid of certain pharmacists to determine the proportion of proprietary articles called for. Out of 2,000 prescriptions it was found that only one in eight were simple mixtures. These simples, together with semi-secrets, constituted 9.3 per cent., and secrets, $3\frac{2}{5}$ per cent. Many of the proprietary preparations were mentioned by name, and criticisms were made on the often conscienceless mode of their manufacture.

Mr. KEENAN remarked that the United States and England were the only countries that allowed a patent on a preparation that is not worked in the country in which the patent is allowed. It was often claimed that these patented articles could be reproduced by any competent pharmaceutical chemist, but, as a matter of fact, such was not the case.

Mr JAMES TAYLOR LEWIS, speaking of the patent law, said that if it could be shown that a patented medicine could not be made according to the formula on file in the Patent Office, then the patent on that article was void.

The Venous Hum in Relation to Blood Count.—Dr. C. N. B. CAMAC read this paper. He said that it was the custom at the clinic of the Cornell Medical College to send all patients thought to be anæmic to the laboratory for blood examination. It was found that many persons with normal blood exhibited a marked pallor; hence no cases were regarded as anæmia unless the characteristic blood changes of that condition were present. The venous hum was audible on both sides, but was most often noted on the right side of the neck. The usual explanation was that the vibration in the walls of the vein was due to a change in the caliber of the vein, giving rise to the formation of a fluid vein; yet he would ask why, if this were the true explanation, was it present in some cases of anæmia and not in others. To foretell it in chlorosis was a safe prophecy. There was an old hypothesis that the hum was due to the thinness of the blood, yet this theory had not received much consideration from medical authorities. It had been recently revived by Potain as a result of certain experiments that he had made. Anæmia might exist without the cervical bruit being present in from 33 to 50 per cent. The relative frequency of the venous hum in chlorotic anæmia pointed to some peculiarity of this variety of anæmia. The author queried whether this might not be due to the known instability of the vasomotor system in such persons. He divided the cases observed into four groups, viz.: (1) Those in which there was a cervical bruit and the hæmoglobin was 90 per cent. or over; (2) those in which this bruit was present and the hæmoglobin was between 75 and 90 per cent.; (3) those in which, with the presence of this bruit, the hæmoglobin was below 75 per cent., and (4) cases in which there was no cervical bruit, and the hæmoglobin was below 75 per cent. Of the twenty-two cases reported, twenty-one had a bruit in the neck. There were fourteen cases in the first group, two in the second, and six in the third group. The important deduction was that pallor, and even the presence of a cervical bruit, did not necessarily indicate blood impoverishment. Again, it was evident that, in some cases, cardiovascular drugs might be more helpful than the administration of iron.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held November 24, 1902.

CHARLES N. DOWD, M.D., PRESIDENT.

Address of the Retiring President.—Dr. FRANK VAN FLEET, in this address, said that one year ago, when taking the office of president, he had expressed a strong desire to bring about the union of the two medical organizations of the State. It was his pleasant duty to say now that the committees of conference appointed to promote this object had held meetings in which the greatest harmony and good feeling prevailed, and that all concerned seemed eager to secure this union of the medical profession of the State. There was reason to believe that the efforts of the committees would in time be crowned with success. The speaker said that 114 new members had been added during the year, and that twenty-four had removed from the county or resigned. The society had continued to be active in the detection and prosecution of illegal practitioners of medicine. The law afforded the community very slight protection in this important particular. The enforcement of the medical laws was laid upon the medical profession. It was true that the fines were turned into the society's treasury, and although they amounted to about two thousand dollars in the past year, the net cost to the society of enforcing the medical laws had amounted to $1,500.

Address of the President-Elect.—Dr. CHARLES N. DOWD presented this address. He said that in the early days of this society the board of censors examined and passed upon candidates desiring to practise medicine. That power had since been transferred to the State Board of Medical Examiners of the State Society. The county society was still working in many ways for the good of the profession and of the community at large.

Inspection of Pharmaceutical Products.—The speaker then took up the question of the relation of the physician to the manufacturing and retail pharmacists. He said that as these products were now too numerous to allow of proper individual examination, it was suggested that the inspection of them should be made by some competent party beyond commercial influences. Many of the profession would be both surprised and pleased to learn that such examination and inspection would be made either by the State Board of Health or by the City Department of Health. This examination would be made free for any physician furnishing the necessary particulars.

Relation of the Medical Profession to Military Organizations.—Under this head the speaker discussed the lack of efficiency of the medical department in the late Spanish-American war, and the apparent need for more power being conferred upon this department in order that there might not be a repetition of the history of that period. Thus, the Adjutant-General's report for that time showed that there were 207 killed and 107 died of wounds, while 4,795 died of disease; in other words, there were more than twelve times as many deaths from disease as from bullets. While there were officers of high rank in large numbers for the army, the medical department was composed of one brigadier-general, five colonels, and seven lieutenant colonels, and this department was dependent upon the quartermaster's department for the transportation of its supplies. From information he had received with regard to the soldiers just returned from strike duty, there had not apparently been much improvement in medical matters in military organizations. The statistics of one regiment during the period of the Spanish-American war were instructive. They showed that, as a result of four months and a half of camp life alone, and without any active service, there were 32 deaths and 373 cases of serious illness. This would mean an annual death rate of 6 per cent., and a morbidity rate of over 71 per cent. In view of these facts, it seemed not unwise for the County Medical Society to endeavor to assist the medical corps of our military organizations in promoting the efficiency of their medical service. In accordance with this suggestion, and on motion of Dr. Wendell Phillips, the president was empowered to appoint a committee to confer with the surgeons of the National Guard as to the best means of equipping the military medical organizations so as to meet the demands of present sanitary science. The following were appointed on this committee: Drs. James Ewing, W. H. Park, L. K. Neff, George G. Ward, and Albert F. Brugman.

The Relation of the Dysentery Bacillus to Dysentery and Summer Diarrhœa in New York and Vicinity.—Dr. W. H. Park presented a communication on this subject. After reviewing the facts connected with the discovery by Shiga of the bacillus bearing his name, and the more recent discovery in Baltimore of the bacillus in connection with the summer diarrhœa of children, reference was made to the recent epidemic of dysentery occurring in Mount Vernon and Tuckahoe. He said that this bacillus was similar to the typhoid bacillus, but did not agglutinate with the serum of typhoid patients. They had taken the blood from twenty-nine cases, and in eighteen of these had obtained a very marked serum reaction, usually with a dilution of one in fifty. Five cases gave an uncertain reaction, and in six there was no reaction. In New York City he had found seven cases of dysentery in the hospitals. Of this number three gave the reaction indicative of the dysentery bacillus. Apparently most of the summer diarrhœa in this city is not due to the dysentery bacillus. Moreover, he believed that the dysentery bacillus gave rise to an affection which was as characteristic as typhoid. In nearly all of the cases there were some of the well-known symptoms of dysentery, *e.g* pain, with blood and mucus in the stools. Just as in diphtheria there might be some cases so mild that it was impossible to say positively from inspection whether or not the disease was true diphtheria, so it was probable that in Baltimore there were some cases of dysentery so mild as not to be recognized as such by the symptoms and signs. A report from Dr. Martha Wollstein showed that in the past month there had been five cases at the New York Foundling Hospital in which there were blood and mucus in the stools, and in these cases the Shiga bacillus was found by Dr. Wollstein. Dr. Park said he did not think the time was yet ripe for giving ordinary cases of summer diarrhœa the serum treatment, although Shiga's reports concerning the serum treatment of dysentery in Japan were very encouraging. In cases of typical acute dysentery, on the other hand, it would seem to be worth while to give a fair trial to this method. The diagnosis should, of course, be confirmed by examinations made by the health department. Epidemics of dysentery were usually closely connected with contamination of the wells by drainage from privies.

The Recent Epidemic of Dysentery at Tuckahoe.—Dr. William A. Payne presented this paper. He said that about one-half of the houses were supplied with New Rochelle water, while the others were supplied by wells. The population of the built-up portion of the town was about 2,300, and many of the people were utterly regardless of sanitary laws. In only four instances did the disease enter the houses of the better class. There is no system of sewerage there. According to the official records, there were twenty-three deaths among children of an average age of three years. The average duration of the illness was two and three-quarter days. Where the disease attacked only one or two members of a family, it was usually found that the members of this family were more cleanly than the average. There appeared to be no connection with the milk supply. These patients suffered at first from malaise, headache, and fever; then the stools became frequent and of a mucous character. Subsequently there was much abdominal pain, and the stools became very bloody. The mild cases lasted from ten to twelve days, the severe cases four weeks, and the very bad ones between two and three months. Vomiting of a mild type was present in 75 per cent of the cases. Pain of a severe character was present throughout the disease. Only one autopsy was obtained at Tuckahoe, and this was by the State officers He had been told that in this case there were numerous small ulcers throughout the intestine, increasing in number from the ileum to the rectum. In this town the mortality was about 5 per cent. Above the age of five years the disease rarely proved fatal, except in the aged and feeble. This epidemic, comprising about 300 cases, occurred during the months of July, August, and September.

Epidemic Dysentery at Mount Vernon.—Dr. F. W Shipman described this epidemic briefly. He said that the disease was not of the amœbic type. The Shiga bacillus was proved to be the specific cause of the dysentery, and this raised the interesting question as to how this organism could have been so suddenly and widely disseminated. The infected district was about one mile wide and eight or ten miles long, and occupied the valley of the Bronx river. In this district there were, perhaps, half a dozen different water supplies, and the Bronx river is not a water supply, but is an open sewer. The first death from dysentery occurred at Mount Vernon on July 8, yet he had not seen any cases of dysentery until July 24, when he had been called to see four cases in different families. The prostration was one of the most noticeable symptoms—indeed, it was most diagnostic. Within twenty-four hours it was found possible to decide whether the case would be mild or severe. The mortality was about the same as at Tuckahoe. The latter place was about the center of the infected district. The results of treatment were largely negative, but hot applications and high saline injections seemed to yield the best results. He had looked up the statistics of Mount Vernon with regard to the prevalence of ordinary diarrhœa, and had learned that it was not so prevalent the past summer as in other years. If, therefore, the Shiga bacillus was the cause of summer diarrhœa there should have been an unusually large number of such cases.

Dr. W. N. Hubbard said that he had treated a small epidemic of dysentery last summer, occurring many miles away from the district already referred to. The average duration of the disease was three or four days, and there was no mortality. In this epidemic the water supply was beyond criticism, though the same could not, perhaps, be said of the drainage.

Dr. Jacob Sobel said that the investigations of both European and American observers showed that summer diarrhœa was due to a number of factors, not only the Shiga bacillus, but streptococci, the pyocyaneus, and the colon and paracolon group, to say nothing of the products of fermentation of food. It was dangerous to assume that all summer diarrhœas were the result of an infection with the Shiga bacillus, but the promulgation of this opinion, erroneous though it was, had proved useful by directing attention to one definite form of diarrhœa. The serum treatment should prove useful as a therapeutic measure, provided there were laboratory facilities at hand to determine what cases should be so treated. It was his opinion that unless the first cases were promptly and judiciously managed the disease would spread rapidly.

Committee on Coroner's Office.—Dr Frank Van Fleet introduced the following resolution which was unanimously adopted:

Resolved, That the President appoint a committee of three or five to inquire into the movement now being agitated to reorganize or abolish the office of coroner in this city; that the committee be directed to confer with other committees and individuals interested in this subject, and to report the fact, with a recommendation, at the stated meeting of this society in December, 1902. Drs William J Polk, J Winters Brannan, and Frank Van Fleet were appointed this committee

Discrimination against Physicians in Licensing Auto-

mobiles.—Dr. Frank Van Fleet moved that the Comitia Minora be directed to protest, in the name of the society, against the enactment of any ordinance taxing vehicles, if it imposes a greater tax upon vehicles owned and operated by physicians than upon vehicles owned and operated by others. Carried.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Held October 8, 1902.

Observations on Malarial Parasites.—Dr. L. B. Goldhorn presented some observations on malarial parasites. In protracted cases of tertian fever, he said, certain forms of the parasites were quite constantly met with which differed essentially from the ordinary ones of the asexual cycle. They took no part in segmentation, and were never seen in recent primary infections. At least two of them were the analogue of the crescentic and ovoid bodies of tropical malaria; they were the macrogamate and the microgametocyte of tertian fever. They were readily recognized when fully developed, in the following manner: in smears stained with chromatin dyes, the male, or microgametocyte, was a rather large parasite with large acromatic zone, in which a mass of unevenly staining chromatin lay in the form of filaments. The parasite's body took the basic dyes poorly, and its coarse, blackish pigment was brought out more distinctly than in any other form. It never had multiple chromatin bodies. In the moist chamber it flagellated, and the flagella originated within a limited area which corresponded to the zona achromatica. Before it flagellated, its usually quiescent pigment became unusually agitated. It disengaged itself from the corpuscular remnant, assumed a spherical form, and flagellated. In stained preparations many variations in the position of the chromatin mass were seen, but on the whole the characteristics remained those given. The female or macrogamete was still larger when fully developed; in the chromatin-stained smear it presented a large well-stained body, with or without a corpuscular remnant, and a small irregular chromatin mass, in an illy-defined zone, situated rather constantly peripherally, rarely ever centrally, but at times just within the body. Its pigment was somewhat finer than that of the microgametocyte. A third form had a round chromatin kernel well within the parasite's body. This kernel was surrounded by a lightly stained reticulated area, which also took on the chromatin dye, and was therefore pink. The body of this form stained well with methylene blue, and it is usually smaller than the two forms just described. The speaker had never seen it extracorpuscularly, and believed it to represent no phase of the schizogony, as he had never met with it in recent primary cases.

Much confusion arose from the promiscuous study of parasites seen in cases of relapse or old cases. Many atypical forms were seen, such as multiple chromatin bodies in young forms, premature segmentation, abnormal position of chromatin, and queer positions of the parasites on the corpuscle. But the number of segments (schizonts) varied even in perfectly fresh cases. As each young parasite received an equal share of the mother's body, and as there was no waste apart from the transformed hæmoglobin and corpuscular remnant, the speaker thought that the number of segments depended upon the size of the infected corpuscle and upon the amount of nourishment it contained. (Double infections of one corpuscle might also be considered, but frequently one parasite atrophied.) As the parasite forming the greatest number of segments might require more time for the completion of the cycle than one forming a small number only, it would by segmenting later fall behind the other parasites. This irregularity, if exaggerated, might influence the length and periodicity of the paroxysms. As a matter of fact, one could find segmenting bodies for some time after a chill, and sometimes the duration of the chill was protracted in advanced cases. By diligent study of animal malarial parasites the speaker had found much which had led to a better understanding of the human malaria. In a paper read before the University Medical Society he described a parasite found in a species of African monkey. He had since had occasion to study the parasite again, and now felt certain that nearly all forms seen by him were gametocytes. What he had said about the staining and chromatin characteristics of the human tertian parasite was, in the monkey, still more clearly defined; and the third form, with karyosome and paler staining reticulated area, was readily found. Febrigenous forms were not seen. Bone-marrow and spleen contained no segmenting bodies. A peculiar notch at the edge of this last (third) form and of the macrogamete was rather constantly observed, and helped to confirm the belief that these third forms were related to the gametes, most closely to the macrogametes. The monkey parasite was probably the analogue of tertian fever. In birds with Halteridium infection one saw the above enumerated characteristics of gametocytes. The staining differences and those in the chromatin were pronounced. The microgametocyte stained very poorly, had a very large central achromatic zone and more or less polar pigment; in the achromatic zone lay delicate filaments of chromatin. The deeply staining macrogamete had, on the other hand, a small chromatin mass, usually at the edge, in a small achromatic zone, and the relatively finer pigment lay all over the body of the protozoon. Dr. Goldhorn said he believed these "hantelforms" to be the analogue of the human estivoautumnal gametocytes, the so-called crescents. Several preparations in his possession showed some details in crescentic bodies which he had not seen demonstrated before. The pigment was removed from these gametocytes and a large achromatic zone became wonderfully distinct; in it lay the chromatin, always in a single body, never split up into segments. As a matter of fact, the speaker had never seen evidence of parthenogenesis in crescents. There were some curious differences in the staining of crescents, some had marked polar staining, others stained lighter blue throughout. It was possible that the one staining deeper might be the female. This year it had been impossible to obtain cases with crescentic bodies, and experimental work that had been planned had to be abandoned. Most instructive material was, however, obtained in the form of tertian cases. Only a brief review of the more interesting cases was given. An old case of one and a half year's standing, with frequent relapses, showed only a few queer young forms and many gametocytes; no parasites with multiple chromatin bodies were found. Another case of seven-weeks' standing, with a rich infection, showed an unusual number of corpuscles with two parasites maturing side by side, or one developing at the expense of the other. A case of a woman from Costa Rica, where the malaria was contracted, was most instructive, because no strictly normal segmenting bodies such as one is accustomed to find in the recent primary infection were seen; instead there were ring forms with a small accessory chromatin body in the thickened portion of the body; or two, three, or even five, unevenly staining, large, round chromatin bodies in a large ring of even diameter throughout. There were never more than twelve segments, usually not over ten, and the parasite's body was always exceptionally small. Yet the case was one of tertian fever. A case with indistinc tmalarial history in a child a little under ten years of age showed large ring-like parasites with a single chromatin body and large achromatic zone with heavy pigment, in a deeply-notched corpuscle, but totally unlike the rings seen in estivoautumnal cases in the crenated corpuscles. It seemed to the speaker that malarial parasites formed what one might term involution forms at a time when gametocytes, which he considered an expression of the necessity of sexual reproduction, made their appearance. The parthenogenetic impulse exhausted itself and the vitality of the febrigenous forms was lowered. We did not know how much the production of possible antibodies might have to do with the phenomenon. That such bodies were formed was reasonable to suppose, as cases of immunity existed, and the study of kindred hæmatozoa (of trypanosoma, for instance) helped to confirm the belief. To-day the practitioner who owned a microscope was, as a rule, satisfied with the finding of the hæmatozoon of tertian fever, but the kind and form and characteristics were not usually considered. As soon as all typical forms had been recognized a better understanding of the asexual cycle and gametocyte formation would be reached. If gametocyte formation could be prevented, transmission of malaria from one individual to another by mosquitos might also be prevented, as the perpetuation of the parasite depended upon them; hence cases containing the more resistent gametocytes would require greater attention and possibly somewhat different treatment than cases of recent infection with immature parasites. The value of positive recognition of mature forms (gametocytes) in tertian fever, therefore, became paramount.

Dr. Ewing said that he had been extremely interested in the facts brought out by Dr. Goldman. He thought that the question of the differentiation of the sexes in malaria was at the present time one of very live interest. He had himself been over much of this ground without, however, getting all the points obtained by Dr. Goldhorn. Some two years ago he had thought he was able to identify the macro- and microgametes, but was not certain, because he was not able to follow the cases through a series of paroxysms. Since that time one writer at least had attempted to differentiate the male and female parasites in the blood (Argutinsky, *Archiv fur microscopische Anatomie*, Bd. 59, 1902.) As the malarial paroxysm progressed the morphology changed and the male and female parasites became clearly differentiated. He could not agree in every particluar with Dr. Goldhorn's conclusions. In the first place, Dr. Goldhorn found that the male stained lightly with methylene blue; in his specimens the male stained darker than the female, though that was possibly due to some difference in technique. He had always found, as did Dr. Goldhorn, that the flagella were extruded from one point in the microgamete, but before the extrusion of flagella he had sometimes seen the chromatin subdivided into four or six groups.

Several Cases of Dysentery Referable to the Bacillus of Shiga.—Dr. Wm. H. Park presented several tubes of cultures of the bacillus of Shiga and of the typhoid and colon bacilli. He had become interested in dysentery while staying at Mt. Desert this summer with Dr. E. K. Dunham and Dr. Flexner. There was an outbreak of a number of cases of dysentery in some of the families living nearby. There were probably twenty cases in all, occurring mostly in children. Dr. Flexner kindly sent to Philadelphia for cultures of the Shiga bacillus, so that, in case of failure to obtain cultures from these cases, they might test the serum reaction. The day the cultures came Dr. Dunham succeeded in getting serum from two children sick with dysentery, and both specimens gave a marked reaction with the cultures from Philadelphia. The same day Dr. Park himself saw a case of dysentery and obtained some mucus directly after its expulsion from the rectum, which he plated, and from which he got the dysentery bacillus of Shiga, which he showed in one of the tubes. This bacillus appeared to have the same characteristics as those isolated by Shiga in Japan and by Flexner in this country and in the Philippines. Dr. Park also presented three tubes showing the growth in the Hiss media of the Shiga dysentery bacillus, and of the colon and typhoid bacilli. The dysentery bacillus remained isolated and did not disseminate through the media nor produce gas. The colon bacillus passed throughout the media producing a general cloudiness, varied by little streaks, due to the passage through the media of gas bubbles. The typhoid also passed throughout the media, but caused no appreciable gas, and therefore left no streaks. This investigation made, therefore, the interesting fact apparent that there was an epidemic in Mt. Desert in which the Shiga bacillus was the exciting factor, giving rise to acute dysentery. On his return to the city, Dr. Park thought it interesting to see how much dysentery was present in New York and how prevalent was the Shiga bacillus. Inquiries made among the hospitals and asylums developed the fact that there was very little dysentery then present in the city. One case, accidentally found, was that of a man who had come from the Philippines three years before, and who, ever since, had had subacute dysentery. For two or three weeks he would be fairly well, never entirely so, and then he would have an acute attack. His blood showed a marked reaction with the Shiga bacillus, and this bacillus, as well as the amœba coli, was found in his stools. This case then seemed to be one of chronic dysentery due to mixed infection with the amœba coli and the Shiga bacillus. Two cases were found, of a man and a baby, who had had dysentery six weeks before, and whose blood gave the specific reaction. In thirty cases in which the blood from suspected typhoid patients was examined, one gave a reaction with the Shiga bacillus. This blood caused agglutination of both the typhoid and dysentery bacilli. The blood of a number of children who had recently suffered from acute enterocolitis did not agglutinate the dysentery bacilli, even when used in a dilution of one part of serum to ten of bouillon. This is interesting in view of the preliminary report from Baltimore, where the Shiga bacillus was abundantly present in the stools of children suffering from acute enterocolitis.

A Solitary Tubercle of the Brain.—Dr. David Bovaird presented this specimen, which, he said, was of rather peculiar clinical interest. The specimen was taken from a girl six years of age, whose family history was entirely negative. When first seen, November 29, she gave a history of having had a fall the previous July. The symptoms dated from that time. Two weeks later there was a loss of power in the right leg, and still later in the right arm and right side of the face. On examination there was found to be a paralysis of most of the muscles of the leg and of the muscles of the arm as well. The tongue deviated to the right on protrusion, and on smiling the right side of the face showed no action. A diagnosis was made of cerebral paralysis. A brace was applied to prevent the dropping of the leg, but the improvement was not satisfactory, and in March she was admitted to the hospital for the correction of the condition in her right leg. Upon her admission her leg was put in plaster of Paris. Finally the child developed symptoms of pneumonia and gradually developed meningitis. The disease ran the ordinary course of tuberculous meningitis and the child died. At autopsy the brain was found generally congested. Over the base of the brain there was a thick, greenish-yellow exudate. In the sulci, especially along the middle cerebral arteries, were multitudes of miliary tubercles. In the left hemisphere, just beneath the upper end of the fissure of Rolando, and about 1 cm. from the surface, was a solitary tubercle, about 4 cm. in diameter. Immediately posterior to this was a second mass, about one-half the diameter of the first. Several bronchial glands were tuberculous; one was calcareous. There were scattered areas of bronchopneumonia in the lung. The viscera was otherwise normal. This case was of especial interest because of the size of the tubercle, which was very unusual for a child of six years—the largest that the speaker had ever seen in a child's brain. The history was interesting as evidence that this solitary tubercle developed as a tumor of the brain, and was responsible for the condition found in the right leg, in the right arm, and in the right side of the face, and that the tuberculous meningitis was a secondary development following the child's admission to the hospital. It was the only case of this character that the speaker had ever come in contact with—a solitary tubercle developing in the brain of a child just as a tumor might have done, and during its early stages entirely devoid of any symptoms pointing to its tuberculous nature.

Mixed Tumors of the Parotid.—Dr. F. C. Wood gave a brief description of two mixed tumors of the parotid which had recently come under his observation. In one of these tumors, which showed a typical endothelial type of growth, there were numerous epithelial pearls containing spine cells. In the second case there was a tumor of long duration, in which flat-celled carcinoma had developed in the substance of a congenital endothelial tumor.

Dr. E. Libman said that during the past year they had had at the laboratory of Mt. Sinai Hospital a case of mixed tumor of the parotid in which they had found distinct areas of epithelioma.

A Case of Traumatic Disease of the Aortic Valve.—Dr. E. Libman showed a heart which had been obtained at the post-mortem examination of a man thirty-three years of age, who had succumbed to an infection by the paracolon bacillus. The history of the case, in so far as it appertained to the heart, were as follows: There were hypertrophy and some dilation of the left ventricle; there was a slight systolic murmur at the apex and over the aortic valve; there was a rough systolic murmur over the pulmonic orifice, without visible pulsation. The second sound was louder over the pulmonic than over the aortic orifice. The murmur was not heard in the vessels of the neck. The diagnosis wavered between several conditions. In the first place, the patient's wife had borne him six children, nearly all of whom had died in early infancy, having been "blue babies." This being taken into consideration, it was thought possible that the patient might have a similar condition, but no one of the usual congenital lesions in itself would very well account for the physical signs present. The possibility of an acute endocarditis, due to the paracolon bacillus, was also entertained. A lesion of the aortic valve, in which the murmur was heard over the pulmonary orifice, was the third diagnosis considered. The relatives of the patient stated that he had been perfectly well up to the age of three years, when he was run over and three of the upper ribs on the left side anteriorly were fractured. After that a very marked cardiac impulse had been noticed, and he suffered from palpitation. It could not be ascertained whether fever was present after the injury or not. The lesion found in the heart was of such a nature that it could only be explained as the result of the traumatism. The anterior and the right posterior flaps of the aortic valve were found torn loose from their attachment to the aorta. There was considerable thickening found at the place from which the flaps were detached, and the two flaps were found to be agglutinated by fibrous tissue with calcareous deposits. Furthermore, there was a line of calcareous tissue running directly across the anterior flap, which also extended down over the endocardium for a distance of about one-half of a centimeter. There was no atheroma of the aorta. One could not help coming to the conclusion that the trauma sustained thirty years before death had resulted in a tear across the anterior flap of the valve, and in a detachment of two flaps from their attachment to the aorta. The question remained open whether the changes found were due in part to an infectious process following the traumatic lesions or not. Professor Prudden had shown that endocardial changes could result after trauma without the occurrence of any infection.

A Case of General Tuberculosis.—Dr. Roper presented this specimen because of the condition observed in one of the ovaries. The patient was a colored woman, aged thirty-seven years. Seven months previously, after giving birth to her fourth child, she had had a slight cough and expectoration. Two weeks after delivery night sweats began, and she lost flesh and had considerable pain in the abdomen. On physical examination there was found to be a distended mass in the abdomen with considerable fluid. At autopsy the retroperitoneal glands were found to be enormously enlarged and tuberculous. There was also a general miliary tuberculosis of the spleen and lungs. The right ovary was filled with numerous large tubercles. The other ovary was normal. The exact seat of the original lesion could not be definitely determined.

Dr. Ewing asked if there had been any intestinal lesions found.

Dr. Roper said there were no intestinal lesions. Dr. Biggs had been inclined to think that the pulmonary glands might have been the original seat of the trouble; but they were but moderately involved, while the retroperitoneal glands were enormously enlarged.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Diseases of the Pancreas and Their Surgical Treatment. By A. W. Mayo Robson, F.R.C.S., and B. G. A. Moynihan, M S. 8vo, 293 pages. Illustrated. W. B. Saunders & Co., Philadelphia, Pa. Price, cloth, $3.00 net.

The Development of the Human Body. By J. P. McMurrich, Ph.D. 527 pages, 8vo. Illustrated. P. Blakiston's Son & Co. Price, $3.00 net.

The Mind of Man, a Text-Book of Psychology. By Gustave Spiller. 8vo. 552 pages. Swan Sonnenchein & Co., L'td., New York. Price, $2.75 net.

Biological Laboratory Methods. By P. H. Mell, Ph.D. 12mo. 321 pages. Illustrated. The Macmillan Co., New York. Price, $1.60.

A Handbook of Materia Medica, Pharmacy, and Therapeutics. By Samuel O. L. Potter, M.D. Ninth edition. Royal octavo, 951 pages. P. Blakiston's Son & Co., Philadelphia, Pa. Price, $5.00 net.

Elements of Chemical Physics. By Josiah P. Cooke, Jr. 8vo, 739 page. Illustrated. Allyn & Bacon, Boston.

Medical News Visiting-List, 1903. Lea Brothers & Co., New York. Price, $1.25.

The Medical Record Visiting List, or, Physicians' Diary for 1903. William Wood & Company. Price, 30 patient, $1.25; 60 patient, $1.50.

The Boy, How to Help Him to Succeed. By Nathaniel C. Fowler, Jr. 8vo, 320 pages. Oakwood Publishing Co., Boston, Mass.

Human Anatomy. By various authors. Edited by Henry Morris. Royal octavo, 1,328 pages. Illustrated. Third edition. P. Blakiston's Son & Co., Philadelphia. Price $6.00 net.

De L'Intervention Chirurgicale dans les Nephrites Médicales. By M. le Dr. Alfred Pousson. 8vo, 100 pages. Illustrated. A. Maloine, Paris, France.

The Practice of Surgery. Third edition. 8vo. By Drs. H. R. Wharton and B. F. Curtis. 1,241 pages. Illustrated. J. B. Lippincott Co., Philadelphia, Pa.

A Text-Book of the Science and Art of Obstetrics. By Henry J. Garrigues, M.D. Royal octavo, 844 pages. Illustrated. J. B. Lippincott, Philadelphia, Pa.

International Clinics. Vol. III, 12th Series. 8vo, 306 pages. By Henry W. Cattell, M.D. J. B. Lippincott Co., Philadelphia, Pa. Price, $2.00 cloth.

The Work of the Digestive Glands. By Prof. J. P. Pawlow and W. H. Thompson, M.D. 8vo, 196 pages. Illustrated. Charles Griffin & Co., Ltd., London, Price, $2.00.

Text-Book of Medical Jurisprudence and Toxicology. By John J. Reese, M.D. Sixth edition. 8vo, 660 pages. P. Blakiston's Son & Co., Philadelphia, Pa. Price, $3,00 net.

A Text-Book of the Diseases of the Ear. By Prof. Adam Politzer. 8vo, 884 pages. Illustrated. Fourth edition. Lea Brothers & Co., New York.

A Treatise on Diseases of the Eye, Nose, Throat, and Ear. By various authors. Edited by Wm. Campbell, M.D. and Jonathan Wright, M. D. 8vo, 1,238 pages. Illustrated. Lea Brothers & Co., New York.

Book Reviews.

Recherches sur les Corps Étrangers du Cœur et des Gros Vaisseaux. Par le Dr A. Marique, Aide du service de chirurgie infantile à l'Hôpital Saint-Pierre. Ixelles-Bruxelles: N. Vandersypen, 1902.

Any contribution to a subject of such importance and interest as this is always welcome. The writer has incorporated in the text valuable tables, in which the principal points of the cases he describes are enumerated. Numerous experiments on animals are carefully catalogued and commented upon. The arrangement is clear and systematic. An extensive bibliography is appended.

A Text-Book of Materia Medica, Therapeutics, and Pharmacology. By George Frank Butler, Ph. G., M.D., Professor of Materia Medica and Therapeutics in the College of Physicians and Surgeons, Chicago, Medical Department of the University of Illinois, Medical Superintendent of Alma Sanatorium, Alma, Michigan; Member of the American Medical Association, Illinois State Medical Society, Chicago Medical Society, Chicago Pathological Society, and Chicago Society of Internal Medicine; Fellow of the Chicago Academy of Medicine, etc Fourth edition, thoroughly revised. Philadelphia and London: W. B. Saunders & Company, 1902.

A work on the subjects of which this volume treats is always of wide interest, for it touches every branch of medicine. The name of the author is a guarantee of the value of this present volume (the fourth edition), in which important alterations and additions have been made. The subject matter dealing with each drug has been carefully reviewed, and all of the modern advances in pharmacodynamics have been interpolated. The more definite knowledge that has been attained concerning the value of certain drugs, especially some of the synthetics, has necessitated various changes. Considerable attention has also been devoted to their incompatibles. Certain chapters, for example those on organotherapy, serum therapy, and related subjects, have been carefully revised and largely added to. An interesting addition is the chapter dealing with the newer theories of electrolytic dissociation and its connections with pharmacotherapy, and also the discussion of the relations of chemical structure to the action of drugs. The writer distinguishes between and treats under separate heads "Untoward Action," and "Poisoning." The Latin accent and quantity of medicinal nomenclature have been given. The Pharmaceutical section has received special attention; but only such drugs which have been proved to be of standard value have been included in the descriptive enumeration. The book has both a general and a clinical index.

Essentials of the Diseases of the Ear. Arranged in the form of Questions and Answers. Prepared Especially for Students of Medicine and Post-Graduate Students. By E. B. Gleason, S.B., M.D., Clinical Professor of Otology, Medico-Chirurgical College, Philadelphia; Surgeon in Charge of the Nose, Throat and Ear Department of the Northern Dispensary, Philadelphia; One of the Laryngologists to the Philadelphia Hospital. Third edition, thoroughly revised. Philadelphia and London: W. B. Saunders & Company, 1902.

The present volume is the third edition of this work. The author states that the book is intended especially for physicians who desire to take a post-graduate course in otology, as well as to supplement the brief course of lectures given to undergraduates in this subject. A number of excellent formulæ are given. The text is concise, though clear.

The Medical Directory of the City of New York. Published by the Medical Society of the County of New York, 1902.

The directory of the County Society appears this year under new editorship, that of Dr. Edmund Prince Fowler, Assistant Secretary of the Society. The general arrangement of the book is the same as in previous years. The inconvenience of double lists, one of all legally-qualified practitioners in Manhattan and The Bronx, and in Brooklyn, and another of the members of the Medical Society of the County of New York, and those of the Medical Society of the County of Kings, is retained, but it is softened somewhat by a difference of type in the two lists, the names in the general lists being in heavy-faced type.

Anatomy and Histology of the Mouth and Teeth. By I. Norman Broomell, D.D.S., Professor of Dental Anatomy, Dental Histology and Prosthetic Technics in the Pennsylvania College of Dental Surgery, Philadelphia. Second edition. Philadelphia: P. Blakiston's Son & Co., 1902.

Like most works upon medical and surgical subjects which have merit this one has required another edition in order to bring it up to present-day requirements. In these days the student [illegible] that any scientific advances or novelties shall be promptly included in the textbooks, which are offered. In the last few years it has become necessary for the dental student to inform himself much more extensively than formerly upon the anatomy, physiology, and histology of the parts with which he is to deal, and, in consequence, the character of the textbooks has greatly improved. This volume is one of the best on its subject, and in its present form meets all requirements. A number of illustrations have been added, and the text has, to a certain extent, been rewritten.

Compend of Special Pathology. By Alfred Edward Thayer, M.D., Assistant Instructor in Gross Pathology, Cornell Medical College; Pathologist to the City Hospital; Formerly Fellow in Pathology, Johns Hopkins University; Instructor in Anatomy, Yale Medical College, and Professor of Pathology and Bacteriology, West Virginia University. Philadelphia: P. Blakiston's Son & Co, 1902.

These little quiz compends occupy their own special niche in every medical library. In the present volume the various systems of the body are considered, with regard to the pathological conditions peculiar to each. This arrangement reduces the labor of research to a minimum. Ewing's "Clinical Pathology of the Blood" has been freely consulted on that subject, and Johnston has written the chapter on the Pathology of the Skin. There is a short chapter on Death by Violence and Poison. The index is quite full and adds value to the book. The work is well calculated to fulfil the purpose for which it has been written.

Essentials of Histology. By Louis Leroy, B.S., M.D., Professor of Histology and Pathology in Vanderbilt University, Medical and Dental Departments. Bacteriologist to the State of Tennessee; Pathologist to Nashville City Hospital; Associate Editor of *Medical Examiner and Practitioner*, etc. Arranged with questions following each chapter. Second edition, revised and enlarged. Philadelphia and London: W. B. Saunders & Company, 1902.

Owing to the rapidity with which the first edition was exhausted, this second edition appears with few changes in the text. There are some new illustrations, mostly photomicrographs. The chapter on Technic has been added to. The essential facts in histology are presented in a compact and convenient form.

The Practical Medicine Series of Year Books. Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Under the General Editorial Charge of Gustavus P. Head, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School. Volume IX, Physiology, Pathology, Bacteriology, Anatomy, Edited by W. A. Evans, M.S., M.D., Professor of Pathology, College of Physicians and Surgeons Chicago, and Adolph Gehrman, M.D., Professor of Bacteriology, College of Physicians and Surgeons Chicago: The Year Book Publishers, August, 1902

The arrangement of this volume is different from that of the rest of the series. The subjects are discussed from the standpoints of various authors, as taken from their writings. The writer's name, with the reference from which his statements are taken, follows the heading of each subject. Thus the volume really comprises in its text a generous bibliography. The editors believe that this plan will prove more satisfactory to the reader, as well as fairer to the views of the quoted authorities. There is a good index. This volume is worthy of its predecessors in this series.

The Nose and Throat in Medical History. By Jonathan Wright, M.D. St. Louis: The Laryngoscope Co, 1902.

The series of papers presented by Dr. Wright during the last year in *The Laryngoscope* have been brought together in book form. The scope of the papers has been, says the author, 'to link together the story of the nose and throat in medicine with the general drift of medical history, with the salient features in the history of civilization and with the general literature which has a bearing upon the central subject of the work." How well this task has been accomplished is well known to the readers of *The Laryngoscope*, and in their present form the results of Dr. Wright's monumental research will become more accessible to the general reader. Nothing like the present series of essays has ever before been attempted, and the work will become a classic in American medical literature. The writer is too well known, both as a physician and as an author, to require any eulogy here. Suffice it to say that out of what might seem to be dry material he has constructed a fascinating story, and added a new wreath to his well-earned laurels.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 29, 1902:

	Cases.	Deaths.
Measles	132	3
Diphtheria and croup	354	38
Scarlet fever	137	7
Smallpox	5	..
Varicella	83	..
Tuberculosis	213	136
Typhoid fever	118	19
Cerebro-spinal meningitis	..	..

Treatment of Typhoid Fever with Castor Oil.—C. C. Bass holds that the serious muscular and nervous symptoms in typhoid fever are, to a very great extent, if not altogether, due to the absorption of toxins from the intestinal canal. The results of the castor-oil treatment prove this, he thinks, clearly enough. Take any case of uncomplicated fever, he says, in which the temperature ranges above 103° F. Give a dose of castor oil every twelve hours, giving no other medicine at all, and the temperature will invariably be reduced; in three days it will generally be below 102°, and always below 103°. Mild delirium will subside in the same length of time. The effects of the oil are confined to the bowel. It eliminates from the intestines germs and toxins which would otherwise be absorbed. Diarrhœa and dysentery are prevented, or checked if they already exist; the disease runs a milder and shorter course, and patients do not lose flesh and strength so fast as they usually do under any other treatment. The last named result is its greatest advantage over any antiseptic treatment. The dose given varies with each case, but may be from one to eight drachms every twelve hours. Enough to act in from three to five hours should be administered, but not so much as to act more than twice. After one or two doses have been given, the amount can easily be regulated.—*St. Louis Medical Review.*

Exophthalmic Goiter; Clinical History and Symptoms of One Hundred and Twenty Cases.—G. R. Murray gives a careful analysis of the cases, though nothing new is brought out. For treatment he advises electricity and exercise in the open air. Thyroid extract he believes to be harmful, but has given thymus extract and suprarenal extract with good results. No special diet is necessary. In his cases belladonna was frequently prescribed but with doubtful results. To be of service in exophthalmic goiter, any line of treatment must be steadily maintained for some weeks or even months, and patients often dislike to continue taking belladonna in sufficient doses to produce physiological effects. Convallaria proved useful in cases in which the frequency of the pulse was very high, and was more effectual in lowering the pulse rate than other cardiac tones. Bromides were useful in cases in which there were marked nervousness and tremors. Arsenic was useful in nearly all cases, and was combined with other drugs with advantage. The best results were obtained by giving small doses of three or four minims of Fowler's solution three times a day for a month or two, or for the first three weeks of each month for five or six months.—*Medical Press and Circular.*

The Presence of Tetanus in Commercial Gelatin.—John F. Anderson reports that of seven samples of gelatin examined one showed tetanus spores. Two samples showed an oval end-spore rod, whose identity was not proved, but in stained specimens it would be hard to distinguish from tetanus, if, indeed, not tetanus with diminished virulence. In tetanus investigations it is important to use freshly-made bouillon, as the organism is apt not to germinate in bouillon over ten days old. The thermal death point of the organism isolated was found to be between twenty and thirty seconds at 100° C. It is important, therefore, that gelatin to be used for injections should be boiled at least ten minutes, on account of the variability of the thermal death points in different species of tetanus. It is suggested that when, as in hospitals, there is likelihood of gelatin injections being used for hæmostatic purposes, the gelatin solution be sterilized by the fractional method on three successive days and kept ready for use in sterile containers.—*Bulletin No. 9 of the Government Hygienic Laboratory.*

A Case of Cretinism Treated with Thyroid Gland.—Ezra Price reports the case of a child of three years, typically a cretin. May 20, 1901, the patient was put upon thyroid-gland treatment, one 5-grain tablet of the desiccated gland being given three times a day. After a month the dose was increased to four tablets a day. Improvement began at once with relief of obstinate constipation and appearance of teeth. Weight increased, the child began to walk, and in about eight months the skin was normal. the hair fine and wavy, the face had lost its dull expression, and the patient acts like other children.—*Indiana Medical Journal.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended November 29, 1902:

THE RÖNTGEN RAY AND ULTRAVIOLET LIGHT IN THE TREATMENT OF MALIGNANT DISEASES OF THE UTERUS, WITH REPORT OF AN INOPERABLE CASE.*

By MARGARET A. CLEAVES, M.D.,
NEW YORK.

IN the recent address in Obstetrics by Dr. J. M. Baldy[1], delivered at the annual meeting of the Pennsylvania State Society, September, 1902, statistics are given, showing the utter futility of any known method of treatment of uterine cancer. From an analysis of the cases of Johns Hopkins Hospital, the most reliable and complete as yet presented in this country, Baldy finds that of 141 women presenting themselves for treatment but fifteen remained alive after six years, some of the patients having died as late as five years after operation. The claim of Volkmann, that after two years' freedom from recurrence or metastases a permanent cure was usual, and that after three years, without exception, such cure was sure to be the case, is absolutely untrue. Labhardt collected 112 cases of late recurrence, *i. e.* after the third year. The majority he found recurred in the fourth or sixth year after operation, and he even cites cases of recurrence in the fourteenth to twentieth year. He substantiates the fact that these were cases of recurrence by showing that they all developed as local growths in the scar from the operation. There is not only an indefinite period of recurrence, as stated by Duplay, but Labhardt also found a late period of metastases in his cases. Baldy concludes that a patient can not be considered cured under six years; hence, he states Johns Hopkins Hospital, since it has been founded, has not with certainty cured a single case of cancer of the cervix. At the Ninth German Congress of Gynecology, Freund was only able to report two cases of cancer of the uterus permanently cured by operation in an experience extending over twenty-three years. Baldy's experience of eighteen years fully bears out these results, and he states that nothing he has seen or heard in the last year has caused him to alter his estimate of but 5 per cent. of cures of cancer of the cervix, made in June, 1901. Recent published statements of Frederick of Buffalo, McMonigle of San Francisco, as well as others concerning the results of their operations upon cancer of the cervix, command earnest attention.

At Saratoga Frederick made the statement that the condition was a fatal one, and supported his avowal by the statistics of McMonigle who, in 481 hysterectomies for carcinoma, had 479 deaths from the previous operation or from recurrence, while Baldy, in June, 1901, at the St. Paul meeting of the American Medical Association, had stated that all of is cervical cancer cases were dead.

Of the dread nature of the disease, no words are necessary. The term cancer conveys it all. The constant and strenuous efforts of the medical profession to find a means of curing or ameliorating it are of common knowledge. There is no doubt that the problem will be an easier one if the pathologist succeeds in telling us what cancer is, and what causes it. But, until that is done, the clinician must proceed in his battle on empiric lines.

"Surgery, the only and best-known cure," says Baldy, holds but a third place in his estimation, and, while waiting for the fruition of other efforts, it must be regarded as the sheet anchor. "In cancer of the superficial tissues, Röntgen rays give promise of some usefulness—how much, is doubtful, and only the future can determine." He regards the results as yet too meagre and uncertain, and states that, so far as it pertains to uterine cancer, absolutely nothing has as yet been demonstrated.

To the writer's mind, the work already done with the *x*-ray, in the treatment of cancer of the superficial tissues, epitheliomas, sarcomas and carcinomas, is of such character as to cause it to be regarded as more than a promise of some usefulness, although the fact is recognized that experience with it is necessary, in view of the almost universal recurrence of this disease.

Johnson and Merrell[2], in August, 1902, presented a résumé of their work, extending over a period of two years. Twelve cures of epithelioma, sarcoma, and lupus are reported. In these cases from one month to two years had elapsed since the last exposure.

The following case is reported to show what has been accomplished in a case of inoperable cancer of the cervix uteri and adjacent tissues, by means of the *x*-ray and chemical rays of light, and in order to encourage its further use in similar cases.

On May 14, 1902, the reader was consulted by M. C., age forty-two years, of English parentage, native of South America, married.

Family History.—Mother lived to age of seventy-five years, and died of liver and heart trouble. Father died of strangulated hernia, at the age of seventy-four years. Patient, one of seven children. Three sisters living and well; one dead of heart disease. One brother drowned and one died of fever. No tubercular, cancerous, or specific history.

Past History.—Patient born and always lived in South America, save for five years spent in a boarding-school in England and a few short trips to France and the United States. Diseases of childhood not known. Malaria at sixteen years, whooping cough at seventeen years. Several attacks of malaria previous to marriage at age of twenty-five years. Menstruation, established at fourteen years, regular every twenty-four to twenty-eight days; as a rule, under time. Duration, three to four days; flow scant, but little pain. No children, but believed to have had two or three miscarriages in early married life. Grippe at thirty years, the only acute illness since marriage. In August, 1900, while patient's husband was under the writer's care, the patient consulted her for an inactive condition of the liver, with constipation, and for this she was treated, with relief. In October, 1890, she was in good general health, save for a leucorrhœa, from which she had suffered more or less all her life. From the last of October, and for the following six months, she suffered from severe uterine hemorrhages, occurring twice a month. These came on at times very suddenly, and were very profuse; color, bright red. Sometimes the flow continued for several weeks at a time. Owing to the revolution in Columbia, the patient's husband was from home, and during these months she looked after their coffee plantation, going farther up the mountain to a sister's house for her meals. This involved much climbing and walking, to which she attributed the hemorrhages, pain in the pelvis, and aching of limbs. At the same time she suffered from vertical and suboccipital headaches.

---

*Read before the Section of Obstetrics and Gynecology, New York Academy of Medicine, October 23, 1902.

In June, 1901, a yellow intramenstrual discharge was established, and patient began to feel very ill and miserable. Owing to their isolated life, no physician was consulted. In August all the symptoms had increased, and the physicians at their port-town ordered, without examination, the administration of hot bichloride douches. His directions were not followed, as the patient began to suffer from hemorrhoids, which she attributed to the hot water. Cool, non-medicated douches were used instead. In August the hemorrhages became less frequent, but the discharge persisted and became very offensive. About this time she began to lose much flesh, became weak, nervous, and every two, three, or more days she suffered from chills, followed by fever and perspiration. Loss of flesh was progressive until treatment was instituted May 15, 1902.

Physical Examination. Inspection. — Medium height, weight 104 pounds, face drawn, haggard, marked cachexia, skin, pale yellowish cast, dry to touch. Conjunctiva and all mucous membranes pale. Tongue coated, breath foul.

Genitalia.—Labial mucous membrane very pale, vaginal introitus constricted, digital examination difficult because of pain consequent upon narrowing of the canal, both from loss of normal elasticity, and by reason of the presence of the friable tissue extending into vaginal fornices, especially in left. Cervix one mass of cauliflower excrescence, which crumbled off at touch and bled profusely; both broad ligaments infiltrated, left more marked than right. Uterus somewhat enlarged and immobile because of pelvic infiltration. Characteristic dirty and ill-smelling discharge. Vaginal mucous membrane in posterior cul-de-sac sloughing off, and vaginal folds or rugæ showing ragged ulcerated edges, the whole bathed in the characteristic dirty discharge, of overpowering odor. Perforation seemed imminent. Speculum examination was attempted, but was not successful, owing to the rigidity of the parts and encroachment by infiltration upon the vaginal canal. Attempt was followed by severe pain and bleeding. Heart's action normal, but weak. Circulation poor. Urine not examined. An examination had been made by the Columbian physician at their port-town, just prior to their sailing for New York, who expressed great surprise that the rectovaginal septum had not given way.

The patient was very feeble, unable to sit up but a few minutes at a time, and able to walk only a short distance, *i. e.* across the street from her boarding-house to writer's office. Obliged to lie down and rest after the slightest exertion. Appetite poor, liver and bowels sluggish, hemorrhoidal veins much enlarged, at times bleeding. She was also very nervous and much depressed. Hemorrhagic discharge every few days, at times excessive. Pain constant through pelvis and down inside of legs.

On the day following the above examination, May 15, and before instituting treatment, the writer called upon **Dr. H. C. Coe, to see** and examine the patient for the purpose of securing a surgical opinion before undertaking the treatment of the case. His findings were involvement of the cervix uteri, infiltration of anterior and posterior vaginal walls, also of broad ligaments, with diagnosis of an inoperable cervical cancer. He said he would not operate upon such a case, and that he did not know a surgeon who would. Treatment was initiated May 15, 1902, by means of a vaginal hydro-electric douche, temperature 100° F., four quarts medicated with 10 grains bichloride of mercury and used at the positive terminal of a source of continuous electromotive force, indifferent contact, fifty square inches in area, to the abdomen, with 40 m.a. of current. This was followed by the use of a general application of the convective discharge of the Franklinic current, for the purpose of initiating nutritive changes.

In instituting the treatment, the mercuric cataphoric douche was given not only for the purpose of cleansing the entire vaginal tract, but to sterilize the tissues more deeply, by the electrical transfer of the mercury into the subcutaneous structures, than was possible by simple irrigation.

On the morning of the 16th she reported less discharge, less offensive odor, and a sense of well-being in contrast to her general feeling. On inspection of the mucous membranes at the introitus, the circulatory conditions were found improved. The treatment was repeated, with 15 grains of bichloride of mercury instead of 10, and 35 m.a. of current. A hemorrhagic discharge began at 4 P.M. of same day. This continued on the 17th, and patient was very weak and faint when she reported for treatment. Because of great weakness, local treatment was not administered, and she was placed on a cot, nude, in the arc-light cabinet. The light of one arc was focussed directly upon the abdomen, especially over the pelvic organs, for twenty-five minutes. This was followed, as before, by the Franklinic current. On the 19th the arc-light bath and Franklinic treatment were repeated. Hemorrhage continued, with but little odor; slight recurrence of chills.

May 20, hemorrhage continued. Treatment with ultraviolet light, the beam projected through speculum to vagina and cervix uteri for ten minutes.

May 21, patient looked very ill and had a severe chill in office, followed by prostration before treatment. Since use of light, flow markedly diminished and odor much lessened. Improved circulatory condition.

Treatment Instituted with X-Ray.—Technique.— Tube enclosed in a box, painted on its interior with many coats of white-lead paint, with an opening for the ray through a series of diaphragms of various diameters, and arranged with a sliding door in the event of having to reverse the position of the tube because of change of polarity of the static machine with which the tube was energized. Patient placed upon the operating table in dorsal position, an ordinary bivalve speculum introduced, and a sheet, 12x18 inches, of tin, with an opening the size of the external part of the speculum, placed over the parts, to shield them from the action of the ray. The buttocks were brought to the extreme end of the table, which was placed within six inches from the opening in the tube-box, and the tube adjusted so that the point of the greatest energy of the rays was directly over the opening in the box, and that, in turn, adjusted so as to bring the opening directly opposite the speculum. An exposure, ten minutes in duration, was made.

May 22, patient had fever the afternoon of the 21st, and is still weak and feverish. Flow very slight; no odor to discharge. During the first two weeks of treatment chills and slight rise of temperature from 100° to 101° F., with great prostration, nervous tremblings, and "rattled" feeling were pretty constant. These phenomena presented themselves much more markedly after the first *x*-ray treatment. On May 21, one week after coming under care, the blood was examined by Dr. E. E. Smith, with the following result: Hæmoglobin (Fleischl), 74 per cent.; red corpuscles, 3,320,000 in a cu. mm.; white corpuscles, 11,560 in a cu. mm.; ratio, 1:287; color index, 1.1; fibrin formation, not increased; morphology of red cells, variation in size, polychromatophilia and fine granular degeneration are apparent.

Differential Count of Leucocytes: Polymorphonuclear neutrophiles, 71.4 per cent.; large mononuclear and transitional, 6.8 per cent.; lymphocytes, 19.4 per cent.; mast cells, 0.2 per cent.; eosinophiles, 2.0 per cent.; myelocytes, 0.2 per cent.; malarial parasites, none, Widal's test.

Hæmatological Diagnosis.—Well-marked anæmia, with pathological leucocytosis.

After four *x*-ray and violet-light applications, the following record was made: (1) Temporary arrest of hemorrhage; (2) diminution and changed character of discharge; (3) disappearance of odor; (4) relief from pain and pelvic discomfort; (5) gain in strength and vigor; (6) loss of extreme cachexia, with return of pink coloring to face and hands; (7) improved appetite; and (8) the appearance of healthy granulations where before a ragged and bleeding fungoid condition of the cervix prevailed. The nodules steadily diminished in size, and the patient progressed favorably in every way. During May and June there were at times frequent, profuse, and alarming hemorrhages, great weakness, and exhaustion. After June, while there were now and then blood stains, there was no hemorrhage. The menstrual function appeared every twenty-four days, as had been her habit. It lasted from three to five days, rarely excessive. In the middle of each menstrual month there were evidences of a good deal of congestion, with slight bloody discharge, until September. With September there was none, and the October period was postponed one week. During this period there was scarcely any perceptible lowering of general tone, as had characterized former periods. There has been no mid-month discharge for October.

It was not until the last of June that it became possible to expose with the speculum the full extent of the destruction of tissue in the posterior cul-de-sac. The rigidity of the tissues had prevented such exposure up to that time.

August 12 the writer obtained the original tube, devised by E. W. Caldwell, for throat work. Following its use a change promptly appeared in the condition of the posterior vaginal wall. The ragged, bleeding folds took on a more healthy appearance, the discharge steadily lessened, and by August 27 every rugæ of the vaginal mucous membrane to the vault had healed and were covered with perfectly sound mucous membrane, normal in texture and coloring. The ulcerated area diminished in size at the same time. The condition of the cervix has varied from time to time. The last of August it was very clear from evidences of disease. In the beginning of this month evidences of cauliflower excrescence again appeared, which were promptly cut down by the intravaginal use of the ray with the Caldwell and Tesla tubes. The nutritional gain has been steady. At no time has there been a return of the odor.

Present Condition.—Appetite and digestion are both good, bowels regular; sleep is absolutely normal. In fact, since the establishment of her treatment she has eaten with zest and slept as peacefully as a child. There has been a steady gain in strength, and to-day she feels strong and well, having no sense of anything being wrong, and goes about as she pleases.

Physical Examination, October 20.—General condition excellent, weight 112 pounds, a gain of eight pounds more than ever before in her life

Abdomen.—Negative on inspection; good note elicited on percussion; liver and spleen normal.

Genitalia.—Mucous membrane of vulvæ at introitus and of vagina, normal in color and character; tissues soft and non-resistant; cervix short on left side, seems almost a continuation of left fornix, somewhat longer on right, of irregular contour, covered with normal mucous membrane, save at point of last heat burn from the anode of Caldwell tube; healing not quite complete.

Cul-de-sac.—Free on right side; left fundus of the uterus drawn over to a considerable degree by scar tissue; fundus normal in size, immobile; no enlarged glands, nor evidence of pelvic infiltration; os patulous; ovaries and tubes not palpable; no nodules in broad ligaments.

During the progress of the case every attention has been paid to the minutest detail of hygiene. The matter of baths, douches, food and drink, fresh air, sunshine, and, as strength returned, exercise, received careful attention. She has been pretty constantly fed on hemaboloids arseniated. Arsenic and iron has been given for a change, but could not be continued long on account of increasing the tendency to constipation. The tendency to hepatic sluggishness has been overcome by the administration of calomel in divided doses, one-tenth every hour, until a grain was taken, three or four times during the time the patient has been under care.

The patient has been buoyed up in every way, and has resolutely set herself to fulfilling directions in order to get well.

The patient has been under care five months and one week, during which time 110 treatments have been given. For the first two and one-half months daily, Sundays excepted, and then three times a week; of these, fifty have been with the *x*-ray and fifty of local light applications. The *x*-ray applications have not been made at regular intervals, but according to the conditions of reaction—thrice, twice, and once a week. Irradiation has been supplemented by intravaginal applications of the chemical rays of light, both at the same sitting, and in the intervals between the *x*-ray seances. The general light bath has been used during the menstrual function, as well as in initiating the treatment, not only to secure the action of the chemical rays, but to bring the organism under the influence of the entire radiant energy of the arc, and permit the inhalations of ozone as well. In this way the entire body has been exposed to all the radiant energies from sources of 4,000 total nominal candle-power (the arcs of 2,000 candle-power each), and the tissues of the patient's body kept under the influence of the light vibrations at a time when the local treatment was prohibited by reason of the physiological function. In three instances the *x*-ray was also used through the abdomen during menstruation. In an experience extending over a period of ten years, with the arc light, the writer had found it successful where other therapeutic measures, medicinal and physical, had failed in improving secondary anæmic conditions, and had treated successfully profound secondary anæmias, cases of pulmonary tuberculosis, as well as other conditions. The improvement secured in incurable pulmonary cases, and the recovery of the curable cases presenting themselves for treatment, as well as the prompt healing of a tubercular ulcer of the larynx, under influence of general applications of the arc light, led to its use in building up the general health of the case in question, and the utilization of the chemical rays to assist in combating the local lesion.

Immediately upon the appearance of a chill, with fever and marked disturbances of the nervous system, the local applications of the *x*-ray were either omitted or given at a longer distance from the tube and for shorter periods of time, in order not to set up conditions leading to the release of more infectious material than the system could throw off. The first chill after the patient came under care followed the first application of ultraviolet light, but it was not so profound, nor followed by so much disturbance of the nervous system, as the one which followed the first *x*-ray treatment. Long use of the Franklinic current in the treatment of chronic disease, had familiarized the writer with the untoward effects following its use, where, from its action, the toxic products of incomplete tissue change, with imperfect elimination, were thrown into the system more rapidly than they were thrown off; hence, from the very outset, the patient was guarded in every avenue from such a result.

Prognosis and Further Treatment.—No opinion is offered as to the ultimate outcome of the case, although from the progress much is hoped for. At the outset the writer told the patient's husband that it would be necessary for her to remain under observation for at least one year. No different opinion is held at the present moment.

The case is not reported as one of cure, but to demonstrate what has been done in a desperate condition and to call attention to the value of the *x*-ray and ultraviolet light in combination, for this class of cases.

In watching the case from day to day, as well as in considering it in retrospect, the writer is free to say that she does not believe the case would have been brought to its present condition without both the general and local applications of light. The technique in future cases will be simplified, by reason of experimental work already done, but both the ultraviolet light and the *x*-ray would be used. For, by the expenditure of the lesser energy, it is possible to keep the diseased area constantly under the influence of vibrations which are inimical to the retrograde cell development, characteristic of malignant disease. In every instance it is an expenditure of energy within the tissues—in the one the energy of the electrical vibrations, in the other the rhythmic short and high-frequency vibrations of light, or, in the latter, the irregular, short, and high-frequency vibrations of the *x*-ray.

Various observers report cases showing the untoward effect of too rapid release of infectious material in the treatment of malignant growths by means of the *x*-ray.

The question may pertinently be asked, What becomes of the malignant tissue and its toxic products. Dr. A. E. Sterne[3] endeavors to throw some light upon this subject. A patient who for a year and a half had had a tumor formation of the glandular structures, especially of the neck region, of enormous size, filling the space between the shoulders and the chin, extending into the chest cavity, and affecting the axillary and inguinal glands, came under treatment. From pressure upon the trachea, breathing had become very difficult and the heart's action was markedly influenced. A noticeable change in the tumor masses became apparent after twelve daily sittings; softening on the side being treated was first noticed, then a gradual decrease in size was noted. Breathing was much easier. When this side was reduced one-half, exposure was discontinued there and begun upon the other side. The patient's general condition improved during this period of about three weeks, and a similar result was obtained on the opposite side. Then attention was turned to the tumors beneath the sternum and adjoining thoracic regions, with like gratifying results. During the latter part of her treatment considerable mental dulness, tremor of the extremities, irregular heart action, persistent bronchitis, diarrhœa, and sweating had been noted. The tumors continued steadily to diminish in size, even after exposure to the *x*-rays had been discontinued, but the spleen which had been carefully kept in view, as steadily increased in volume. The *x*-ray exposures were stopped altogether, and every effort used to counteract the overwhelming empoisonment of the entire system. But the efforts were fruitless. The tumors continued to diminish until they had practically disappeared; the spleen, however, continued to increase until it reached the brim of the pelvis, the liver, too, augmented in volume, the patient grew more and more weak, until finally coma ensued, convulsions set in, and the patient died with every mark of violent general sepsis, not only clinically, but microscopically demonstrated through blood changes. One of the tumors was examined, and was found to be as first diagnosed—a small-celled sarcoma. A control examination gave the same result.

This case has been detailed at some length because it is most instructive. The *x*-ray by its action upon the more unstable molecules and compounds of the morbid tissue, destroyed them, but the decomposed toxic material of these tumors destroyed the patient's life. Dr. Sterne very justly points out that a slower, more intermittent treatment, would have had less disastrous results, for the system might have been able to throw off the septic material more gradually. The *x*-ray exposures were stopped before the tumors had disappeared, and still they continued to melt away. This shows the cumulative effect of the agent which in the use of electricity is familiar to every electrotherapeutist. An expenditure of electrical energy may be made in the tissues of patients up to a certain point, *i.e.* a point approximating normal metabolism, to a patient's good; and improvement will not only maintain itself, but go on to a greater nutritive activity, with improved function after its cessation. Doubtless energy is stored in the supreme nerve centers and ganglionic nerve cells which tends to further promote nutritive changes.

Pusey reports a case of extensive carcinoma, involving all the structures in and around the orbit of the right eye, which had progressed into the cranium when the treatment was begun. Two months' treatment resulted in great amelioration in the condition for a while, in both the appearance of the growth and the pain, but later evidences of rapid intercranial growth appeared and the treatments were discontinued. In the second month of treatment the *x*-ray effects were pushed to the point of producing *x*-ray irritation, the tumor increased and localized, and excruciating headaches appeared. The character of the headache indicated that the tumor was developing rapidly in the meninges, and as the disease was progressing even where the *x*-ray effect was greatest, and apparently was uninfluenced by the treatment, Pusey concluded that the case was certainly beyond control, and that further treatment was useless. On November 23, 1901, the man was discharged, having at the time an acute *x*-ray inflammation over the whole involved area. There seemed every reason to believe death imminent. Five months later Dr. Sprague of Sheffield, Ill., sent the following letter to Pusey: "Dear Doctor: I write you regarding the condition of Mr. ——, an old gentleman whom you treated for carcinoma of the right eye, discharged as incurable (if I am correctly informed by Mr.——) about the last of November. He was a charity patient, and I think was referred to you by Dr. Wilder. He called on me on his return from Chicago, had a recipe calling for tablets of a quarter of a grain of morphine, to be taken when in pain. I saw that he had about twenty tablets. I noticed the condition of his eye at that time, and concluded from my examination that it was only a question of time, and a short time at that, with him. I saw him yesterday, and he presents an entirely different appearance. The mass that occupied the orbit has shrunken, allowing the lids to close. He is free from pain, eats and sleeps well, uses no anodyne. There are a few little nodules on the nose near the commissure of the eyelids. With that exception he looks quite well. He has certainly gained since coming home, and I feel assured it is the result of the *x*-ray treatment. I should like you to see him again, but, of course, his means being limited, he would have to go to the Eye and Ear Infirmary as before."[4]

This case demonstrates that the action of the *x*-ray in producing progressive and long-continued ill effects, characteristic of *x*-ray-injuries, may, on the other hand, serve to influence progressively the retrograde influence set up in malignant growths. At times the vaginal mucous membrane left exposed by the bivalve speculum has been protected by means of strips of tinfoil, but, as a rule, no effort has been made to cover it, and part of the time the *x*-ray has been used with the cylindrical glass speculum which was blown for the writer to use in connection with the ultraviolet light. But, while this has been my practice, I do not advise the leaving of the healthy tissue unprotected, nor the use of a glass speculum for the purpose. In all medical work the individual factor is of such moment that one can not assume the responsibility of recommending to others a seeming lack of proper precaution. The writer has not found the mucous membrane more susceptible to the action of the ray than the skin. But, on the contrary, the danger of systemic absorption and sepsis she believes to be greater in the mucous membrane, because of the more direct and intense action upon the morbid growths, as well as from the abundance and proximity of the lymph channels. At no time has there ever been any tendency to an *x*-ray irritation upon the healthy mucous membrane or about the introitus. The only trouble has been in using the special tube devised by Mr. E. W. Caldwell for throat work. In this tube the anode becomes so hot that on three occasions a heat burn has been produced, which, however, has promptly healed without untoward effect. This action was at first attributed by the writer to the metal speculum or shield provided with the tube. It was therefore discarded as unsuitable. Similar burns have been produced twice since, however, showing that they were due to the heating of the anode. For the last week a Tesla tube has been used. As it is only provided with a cathode, the patient serving as anode, there is no danger of undue heating effects. The positive terminal of the machine is grounded, and by insulating the patient the high-frequency discharge accompanying its use is obviated. During the more active progress of the disease, the writer believes that the profound molecular as well as mechanical effect of the high-frequency discharge tends to increase the danger of too rapid release of septic material. When this stage is passed, it may be used additionally, for the patient's good. The improvement in this case was established by the use of an ordinary *x*-ray tube, and the short, high frequency waves or ultraviolet rays of light, and the technique of treatment was evolved step by step as the case progressed. At first the outlook seemed so hopeless that there was little to stimulate especial effort in securing the best means to the end. With the progress of the case no effort has been spared to perfect appliances, and at this time it is possible that similar cases would make much more rapid progress.

Exposures were made with the ordinary tube, at a distance from six to ten inches from the target, and for from five to ten minutes. With the Caldwell and the Tesla tube the applications have been from one to five minutes, with an average of three minutes. With these tubes there has been no effort to protect the vaginal tract, and all the tissues from the introitus to the cervix and vaginal vault have been brought directly under the influence of the *x*-ray vibrations, while the penetration, especially with the modified Caldwell tube, must profoundly influence all the pelvic tissues.

The writer prefers to use the Caldwell tube without a Ferguson's speculum, so as to secure the action not only on the cervix, but upon the entire vaginal tract, especially in the fornices and cul-de-sac.

The heating of the anode has, as has been pointed out, caused slight heat burns, but the tube is now being constructed so as to permit of its use without burning and without using a speculum, a detailed description of which, by Caldwell, will appear in the *New York Medical Journal* of an early date.

The Tesla tube should preferably have a long, well-insulated handle of hard rubber, to cover the tube as a shield to the introitus. This, for two reasons: (1) To prevent the operator from being exposed to the action of the ray, and (2) The high-frequency discharge. The *x*-ray energy is much less with the Tesla tube now in use than with the Caldwell. The vacuum tube electrodes, which the writer has in daily use for percutaneous, intraaural, nasal, vaginal, rectal, urethral, and intrauterine applications, when connected with a multiple spark-gap, give not only the characteristic vacuum-tube discharge, but a true *x*-ray effect as well, demonstrable with the fluoroscope. A localization of the *x*-ray energy within the cervix to just beyond the internal os is in this way possible.

The best results cannot, in the writer's opinion, be secured without direct intravaginal and uterine localization. The chemically-disorganizing action of the *x*-rays in the tissues of the human body, assuming that the chemical substances encountered have equal stability, should diminish with the depth, partly by reason of the increased distance from the radiant source, or anticathode, and partly by reason of increased absorption and attenuation at each successive layer of traversed tissue. Hence, the nearer the seat of the lesion the *x*-ray energy is expended, the better the result.

The physiological effect of the ultraviolet rhythmic light, from all the evidence secured, does not differ, save in degree, from that of the ultraviolet jangle of the *x*-ray. It is shown that the "histological changes do not resemble those produced by burning or cauterization; that certain cells are acted upon, and the process resembles a microbiosis." The first point of attack Sack[5] has shown to be the blood vessels. Cells which are not hopelessly diseased are capable of undergoing a retrogressive metamorphosis under the influence of light. The action of the *x*-ray is more intense, and with it there is danger of producing disastrous results if pushed too far. Therefore, the best results are to be secured by the use of the light energies during the intervals of irradiation, in order that the diseased tissues may be constantly influenced. The use of both of these agents should be considered, not only in inoperable, but in operable cases, and in the latter should at least follow the use of the knife, for carcinoma cells are often left in the deeper strata, which cannot be reached by the knife.

Hopkins[6] reports a case of cervical cancer brought to him on a stretcher, with profuse bleeding, in which the x-ray and light were used, with control of hemorrhage and improvement of the conditions.

Stuver[7] reports a case of cervical cancer, with involvement of vaginal walls, excessive discharge, and great debility, in which he used the x-ray through the speculum, with marked amelioration.

Skinner[8] reports twelve pelvic cases in all, and a fibrosarcoma of anterior abdominal wall, recurring after extirpation of uterus and ovaries for original lesion.

The fibrosarcoma of the anterior abdominal wall, secondary to the removal of the uterus and ovaries for the original lesion, had been under care nearly eight months, and had been rayed eighty-five times. The patient had so far improved as to be able to resume her duties as a teacher. In a tumor of left broad ligament, with ascites, an inhibitory action upon the growth, with improved general health, had been secured. In two cases of uterine cancer with involvement of adjacent tissues, a like inhibitory influence seems to have been established after six weeks' and three months' treatment respectively. Two similar cases were treated three and eight times respectively. The former without effect, the latter was reported as having derived some benefit. One uterine cancer, with involvement of vaginal vault and bladder, is still under care, but up to time of report maintained improvement but four days at a time, when all the untoward symptoms reappeared. Five other cases, four of carcinoma, with involvement of adjacent tissues, and one of sarcoma, died from toxæmia and exhaustion in from one to three months after coming under care. One, a small, nodulated, palpable tumor, probably sarcomatous, situated deeply in the lower lumbar and upper sacral regions, was, during a period of four months, rayed thirty times, with complete relief from pain and diminution in size. At the end of this period she was operated upon for tubal pregnancy, when an examination of the original malignant mass demonstrated that three nodules, the size of a pea, were all that was left. The future of this, with that of the case of fibrosarcoma of the abdominal wall, Skinner states will be watched with interest.

Professor Lorenz's Fee.—Dr. John Ridlon writes to the *New York Medical Journal* that Dr. Lorenz receives a fee of thirty thousand dollars for operating on the Armour child. This includes the services of his two assistants and also the after-treatment in Chicago and in Vienna when the plaster splint is removed.

PULMONARY SYPHILIS SIMULATING PULMONARY TUBERCULOSIS.*

By HENRY W. BERG, M.D.,
NEW YORK.
ATTENDING PHYSICIAN TO THE WILLARD PARKER HOSPITAL· ADJUNCT ATTENDING PHYSICIAN TO MT. SINAI HOSPITAL.

Pulmonary tuberculosis is so frequent a disease that it is not surprising that other non-tuberculous pulmonary lesions resembling those produced by the tubercle bacillus are frequently mistaken for it. This is especially the case with syphilitic disease of the lungs. In the past ten years I have seen a number of cases, of which the following history may be a type, which revealed a general history of syphilis and the physical signs of pulmonary phthisis, but generally followed a course which seemed to differentiate them from cases of pulmonary tuberculosis. The history which I select as a basis for this paper is as follows:

June 15, 1902.—Mr. I——, Lithuanian, metal, worker, twenty-eight years old; no tuberculous history in family; had chancre eight years ago; treated abroad for three or four months with drugs; no inunctions; some three years ago was married; no children; wife has had a possible early miscarriage; some two years ago began to cough; at the same time loss of appetite, increasing pallor, fever, night sweats, loss in weight; has lost almost thirty pounds in two years; was under the treatment of several physicians during that time with no effect; progressive emaciation; has continued at his business, although he has been unable to work steadily; during most of this time has expectorated a thick sputum; doctors examined it; does not know the result of examination; some six months ago had a severe hemorrhage; before that, occasional streaks of blood after a straining cough; says he "coughed up a half pint of blood in twenty-four hours"; another hemorrhage, not so severe, two weeks ago; all of the physicians have told him that his lungs were affected; one physician told him he had consumption.

Examination.—Six P.M.; patient about five feet four inches in height; very thin, emaciated, weight about 125 pounds, with clothing; pale and anæmic; hair very thin, phthisical facies, temperature 102°F. in mouth; respirations, 32; pulse, 86; tongue coated; speaks rapidly.

Physical Examination.—Right lung—auscultation—upper lobe, anteriorly, râles (crepitant and subcrepitant), high pitched, almost tubular, breathing up to three inches below clavicle; respiratory murmur better, but with prolonged, expiration above clavicle; respiratory murmur below level of third rib, normal; some coarse râles heard in suprascapular region on the right side; otherwise posterior surface of lung, normal; respiratory murmur heard over supraclavicular portion of apex of lung one-half inch lower than level of respiratory murmur over supraclavicular portion of left lung; percussion—dull percussion note over upper lobe of right lung as low down as third rib anteriorly. Pulmonary resonance good below that level; over supraclavicular portion of lung on right side dull percussion note when compared with opposite side; percussion shows supraclavicular portion of apex about one-half inch lower on right side than on left; pulmonary resonance—over upper lobe of right lung posteriorly—dull note; resonance over the remainder of right lung and whole of left lung good; heart, normal to percussion; accentuated second pulmonic; faint systolic, blowing murmur over pulmonary area; spleen percusses to free border of ribs, not palpable; complains of suffering from occasional diarrhœa;

*Read before Section on Practice of Medicine, New York Academy of Medicine, November 18, 1902.

no blood or mucus in stools; no stigmata of syphilis on surface of the skin; lymphatic glands at the neck epitrochlea and groin, enlarged; chronic nasal catarrh; speaks of hair having fallen out extensively when his illness began, but it does so no longer; hair is readily removed by slight traction; no mucous patches in mouth or pharynx; no destruction of tissue in palate or pharynx; is somewhat hoarse; vocal cords congested, probably as a result of cough; sputum examined, no tubercle bacilli found. This patient came to my office at first about every third day; later on, every week, and recently only once in two weeks. His treatment consisted of small doses of morphine for his cough. Iodide of potassium in 20 to 30-grain doses t. i. d., plentifully diluted with vichy, and the bichloride of mercury in $\frac{1}{20}$ grain doses; in the beginning, four times a day; later on, three times a day. A liberal quantity of milk was advised and taken; other food, as his taste dictated. His appetite gradually improved. He resumed his work after a rest of two weeks; his fever gradually left him; his cough diminished, and his night sweats ceased in the second month. He gradually improved in weight; when I last saw him, three weeks ago, he weighed 145 pounds, having gained twenty pounds. He is still anæmic. The physical signs of the pulmonary disease present when I first saw him have gradually disappeared. There are now no auscultatory signs of consolidation present, with the exception of occasional moist râles over right apex, which clear up when the patient coughs. Percussion reveals no abnormal signs, save a slight dulness anteriorly immediately below the clavicle; apex of lung (supraclavicular) still percusses lower on the right than on the left side; patient sleeps well at night; nasal catarrh has disappeared; lymphatic glands still enlarged; hair on head still thin; face shaven smooth.

From this rather imperfect history, I think we may conclude: (1) That the patient has practically recovered from his pulmonary disease, and (2) that, having recovered under antisyphilitic treatment, including medium doses of the iodides, under which a tuberculous lesion would probably have grown worse, and the history showing that the patient was a syphilitic subject, the pulmonary lesion was a manifestation of his general syphilis.

I have thought it desirable to present this case to your consideration, not because the condition with which it is connected is in any sense a new one, but because I am led to believe, from my experience with similar cases of pulmonary lesions in chronic syphilitics, that the condition is not nearly as rare as is generally supposed. I believe such pulmonary complications of syphilis are sufficiently common to make the subject of great importance, both to ourselves and to our patients. This is the more true from the fact that pulmonary tuberculosis, which this condition so closely simulates clinically, is so frequent a disease that cases suffering from the rarer condition of pulmonary syphilis are in danger of having the latter lesion overlooked, and the syphilis not treated. The inefficacy of the treatment for a tuberculosis of the lung which does not exist is a foregone conclusion.

The absence of tubercle bacillis in the sputum so frequently occurs in early cases of true pulmonary tuberculosis that this, in itself, would scarcely arouse our suspicion of some other process being operative in the affected lung. On the other hand, the omnipresent tubercle bacillus would find so favorable a nidus in a lung, the seat of syphilitic disease, that even its presence would not positively exclude pulmonary syphilis.

In order, however, to avoid a desultory discussion of this subject, it will be wiser briefly to consider the main data of our knowledge of pulmonary syphilis. First, then, as to the frequency of this lesion. All authorities, with the single exception of Paneritius, who have written concerning specific disease of the lungs, agree in the conception that the condition is rare. This belief is founded upon the rarity of finding syphilitic lesions of the lung at autopsy. They carefully exclude any cases except those in which gross lesions of the lungs of a syphilitic character are found post mortem. Given a general syphilis, with post-mortem findings of pulmonary tuberculosis, and it is assumed that the syphilis took no part in the development of the pulmonary lesion. As well might one exclude, in a case of bronchopneumonia complicating a diphtheria, the agency of the diphtheria bacillus in the production of the pneumonia because it is well known that such pneumonias are the result of a mixed infection by the pus organisms plus the diphtheria bacillus. Furthermore, it seems illogical to limit the term syphilitic pneumonia, or syphilitic pulmonary disease, to cases showing the characteristic gross lesions of such syphilitic pulmonary disease, and exclude from such classification pulmonary lesions due in their inception to syphilitic changes in the walls of the blood vessels supplying the affected areas of lung tissue; excluding, for instance, such lesions as specific endarteritis, which plays an important rôle in the specific lesions of the brain and spinal cord. As I have said above, it would hardly seem proper to exclude even all cases of pulmonary tuberculosis affecting syphilitic subjects, for the tuberculous process may be in the nature of an infection which has found its favorable nidus in a lung originally the seat of a comparatively minute syphilitic lesion of the bronchi or blood vessels supplying the alveoli. It may be claimed in such cases that the practical value of a knowledge that the origin of the tuberculous pulmonary infection was in such a syphilitic nidus, is not great, since it is the tuberculosis that we have to treat, and not the syphilis. But is it not a cardinal principle in the therapy of tuberculosis that it is of primary importance to improve the patient's general health to its maximum point? What can be a greater deteriorating factor than an uncured syphilis? That pulmonary syphilis, complicated by pulmonary tuberculosis, is a far more frequent condition than is generally believed appears from a consideration of the frequency of both tuberculosis and syphilis. Thus, Andvord, (*Norsk Magazin for Lægevidenskaben*, 1902, No. 5) calculates that one out of every three or four individuals under eighteen years of age has latent tuberculosis. Naegeli's post-mortem records in 278 autopsies showed 215 with latent tuberculosis. Surely, then, the frequency with which syphilis is added to this latent tuberculosis is the determining factor in making the latter process active in the lungs. The signs of pulmonary disease occurring in the course of syphilis, especially late in the disease, should place the physician on the *qui vive* as to the connection between the syphilis and the pulmonary manifestation present in the individual case.

Pulmonary syphilis may be a manifestation of congenital syphilis, the lung being the seat of a connective tissue hyperplasia a fibrosis of the lung with occlusion of terminal bronchi and atelectasis of large sections of lung tissue. It may also be a manifestation of acquired syphilis. It is to this later form of the affection that this communication is devoted. Such acquired pulmonary syphilis may be present in the secondary or tertiary stage. The more or less subacute variety of syphilitic pneumonia and syphilitic bronchitis, properly so-called, is apt to be a condition of the secondary stage of syphilis, while the other forms of pulmonary syphilis are present as one of the manifestations of later tertiary lesions. Pancritius ("Lungen Syphilis, 1881), in his classical work, believes all acquired pulmonary syphilis to be a manifestation of the secondary stage of the disease. Stenosis of the bronchi, due to infiltration and thickening of the walls of the bronchi by gummy masses, is an occurrence of tertiary syphilis. Gummy tumors of the lungs are found chiefly in the later stages of syphilis.

Pathology.—It is of interest to discuss the types of morbid changes found in pulmonary syphilis. Most authorities who have had opportunities of making autopsies of syphilitic pneumonias, so-called, have found lesions of the following characters, which, while rare, serve to indicate the changes produced by a long-continued syphilitic involvement of the lung going on to the production of gross lesions and resulting fatally.

In acquired pulmonary syphilis, a catarrhal bronchitis has been, perhaps, the most frequent finding, clinically. Such bronchitis is present in the early secondary stage of syphilis, is more or less local, and generally subsides under active antisyphilitic treatment. Patients dying in the tertiary stage of syphilis have shown, however, not infrequently, a stenosis of the small and large bronchi, and even of the trachae. This is due to a cicatricial narrowing of the bronchi. Gummata have been found in the walls of the bronchi infiltrating the submucous tissues; such gummata undergo fibrous changes, resulting in cicatricial bands, which produce the stenosis. Such stenosis, if complete, is followed by atelectasis, of air cells supplied by the stenosed bıunchos, while it is possible for a bronchiectatic cavity to develop in the bronchus on the tracheal side of the stenosis; such bronchiectasis will give the physical signs and other symptoms due to the presence of such a cavity produced as a symptom of tuberculosis. Gummata are found in some cases more rarely scattered throughout the lung in small or large numbers, and range in size from one-eighth of an inch to several inches in diameter. These are sometimes, although rarely, seen upon the surface of the lung. They are more frequent in the substance of the lung around its root, and are apt to follow in their distribution the course of the bronchi and the larger vessels. The gummata are more frequently found in the lower lobes.

They are apt to be surrounded by a small area of inflamed lung tissue, having a tendency to undergo a fibrous degeneration, which spreads in fibrous bands through the interalveolar connective tissue, causing contractions, and sometimes a fibrosis of limited areas of lung tissue. Pulmonary gummata, however, may undergo a softening degeneration somewhat like that of caseous tubercles of the lung. Such soft degenerated gummata may be discharged through a bronchus, and thus give rise to the formation of a cavity.

Dr. Councilman (*Johns Hopkins Hospital Bulletin*, Vol. II, No. 11, 1891) says that the initiation of a pulmonary gumma consists of a pneumonia with exudation into the alveoli of a limited area, of a fibrinous material; this, together with tissue of the alveolar walls, undergoes a fibrous change, which finally breaks down in a necrotic and caseous process. The walls of the capillaries and small blood vessels become less elastic, and their lumen is much narrowed. Around the blood vessels and bronchi connective tissue bands are formed, and in such places the walls of the alveoli show similar thickening.

Cases of true pulmonary syphilis have been described in which there is more or less general connective tissue proliferation, extending from the root of the lung around the blood vessels and bronchi, forming a true fibrosis of the lung; this may involve almost the whole of one lung, or a lobe of a lung, or may occur in isolated patches scattered throughout the lung, with intervening areas of healthy lung tissue.

Dr. Herman Weber (Pathological Society Transactions, XVII, 152) describes a case which shows another method by which syphilis may involve the lungs, and that is through the bronchial lymphatic glands. The glands were much enlarged, some an inch in diameter; the pulmonary lymphatics, leading from them were dilated and full of a creamy fluid. From a cross section of the larger glands a creamy fluid exuded, which consisted of fat globules and granular bodies undergoing fatty degeneration. Finally, writers speak of a slowly developing, more or less disseminated lobular or bronchopneumonia, which may result from syphilis (Pancritius-Lungen syphilis, 1881). Such areas of bronchopneumonia result in connection with the breaking down of a large gumma of the lung or adjoining organs (Delépine and Sisley, Pathological Society Transactions, XVIII, 141), or degenerated and softened syphilitic bronchial glands.

I do not find any authorities who speak of post-mortem findings which would point to a general phthisical process in the lungs originating in a gradually developing thrombosis of pulmonary capillaries due to syphilitic endarteritis; and yet such syphilitic endarteritis is known to be a frequent pathological entity in connection with cerebral syphilis. It is true that the circulatory conditions in the lungs, as compared with those in the brain, are very different. The anastomosis between the pulmonary capillaries is very much more plentiful than in the brain.

Yet the frequent occurrence of infarcts of the lung, due to emboli and thrombi of well-known origin, proves that the anastomotic circulation is frequently insufficient to supply an area of lung which has been deprived of its circulation by the occlusion of its supplying vessel. It may be that the occlusion of a vessel occurring as a result of a syphilitic endarteritis is too gradual to produce an infarct, but surely it is logical to believe that such occlusion is sufficient to produce a subacute bronchopneumonia that sets in action the series of changes, that finally result in syphilitic pulmonary phthisis.

It is with a view of confirming such a possibility that post-mortem examinations should be directed; for such areas of pneumonia, while originally due to syphilis, could very soon undergo a tuberculous degeneration. This is all the more probable when it is remembered how very large a proportion of human beings have latent tuberculosis. A tuberculosis thus implanted upon a syphilitic bronchopneumonia due to a specific endarteritis, would naturally show tubercle bacilli in the sputum, in addition to the history and the symptomatology of syphiles. Such a case could not possibly be differentiated from pulmonary tuberculosis pure and simple, and yet it would be just as important to treat the syphilitic element which was active in the production of the original lesion as it is to treat the syphilis which has caused the paralysis in an endarteritis of a cerebral vessel. I do not agree, therefore, with Fowler and Goodlee ("The Diseases of the Lungs," London, 1898), who, in their excellent work, claim that the presence of tubercle bacilli in the sputum absolutely precludes the possibility of pulmonary syphilis. On the contrary, I believe that when positive syphilitic lesions exist in other organs and tissues, with a clear history of syphilis, and especially if the patient has had insufficient treatment for syphilis, the presence of pulmonary disease, subacute or chronic in character, even if tubercle bacilli are present in the sputum, demands that the patient shall have the benefit of an antisyphilitic treatment, at least with the object of ridding him of the deteriorating influence due to the syphilitic infection, and thus enabling the remedies directed toward tuberculosis to have their due effect. It seems illogical to recognize the utility of treating the general bronchial catarrh so frequent in the early secondary stage of syphilis on the antisyphilitic basis alone, although the evidence that such bronchitis is due to syphilis is only clinical in character, and to deny to the beginning localized pulmonary changes in the tertiary stage of syphilis the protection of a similar antisyphilitic cure, because we have no positive evidence to show that such incipient pulmonary changes are syphilitic and not tuberculous.

This brings us to a consideration of the symptoms which we can marshal to support the view that a given case of pulmonary lesion is syphilitic in whole or in part. These symptoms, as a whole, are not alike in every case, nor are they sufficiently characteristic as a group to make the diagnosis of syphilitic disease of the lungs, as differentiated from other pulmonary diseases, positive. Very frequently we shall have to call in the somewhat fallacious method of reasoning *post hoc, proper hoc*, and place more reliance than we would wish upon the success of the antisyphilitic treatment as an evidence of the existence of syphilitic pulmonary disease. This is true, however, also of syphilis of the brain and other organs, especially those concealed to palpation and sight. Indeed, even cases of syphilis of the liver frequently depend for the confirmation of the diagnoiss upon a favorable result from antisyphilitic treatment.

The cases I have seen, in which I suspected syphilis of the lung, and the cases of which I have read, were of these types: (1) Those resembling pulmonary phthisis of the tuberculous type; (2) Those resembling subacute or chronic pneumonia of the ordinary type; (3) Cases of pulmonary gummata, combined with the formation of more or less extensive fibrous bands and adhesions; (4) Cases in which, in combination with extensive syphilis of other organs, particularly the liver and the bronchial glands, the lungs become the seat of one or more abscess cavities, due to the breaking down of such syphilitic bronchial glands, pulmonary gummata, and gummata of adjoining organs. Cases belonging to the third and fourth groups I have not seen. I speak of them owing to well-authenticated reports of autopsies made on such cases by numerous observers. I have seen several cases of the first and second class.

The symptoms of cases belonging to the first group are essentially those of pulmonary tuberculosis, with the additional important factor present in all classes of syphilitic pulmonary disease, namely, the presence of an undoubted syphilitic history, and with syphilitic manifestations in other portions of the body. When the individual symptoms are considered, however, there are variations from those present in pulmonary tuberculosis. The cough is not so constant or persistent, owing to the small amount of sputum; hemorrhages are not as frequent, although they occur; hectic fever is not as universal, although it does occur, especially if bronchiectatic cavities filled with purulent secretion are present; loss in weight is a common symptom, but not as marked as in tuberculosis; the anæmia is not as great as in tuberculous phthisis; the loss in strength is less in evidence in the specific than in the tuberculous cases; night sweats are rarely complained of in syphilitic cases.

The physical signs obtained by auscultation percussion and palpation of the chest are those which correspond to the physical changes which the lung has undergone, and are the same signs which would be present were the physical changes caused by tuberculous lesions. There is rarely, however, a fetid odor from the breath of the patients belonging to this class of cases, even those cases in which a bronchiectatic cavity can be mapped out on careful physical examination. It is more frequently found that pulmonary syphilis shows its earliest manifestations in the lower lobes or at the root of the lungs.

In my own experience, however, the upper lobe of the right lung is frequently involved. The presence or absence of tubercle bacilli in the sputum depends upon whether the case is one of pure syphilis of the lungs or whether a tuberculosis has been engrafted upon a syphilitic process in the lung. The absence of tubercle bacilli in the sputum, with advanced pulmonary changes, is an important negative symptom, while the presence of bacilli in a case of slowly progressing pulmonary disease with a typical syphilitic history does not exclude the necessity of placing the patient upon an antisyphilitic regimen.

Syphilitic phthisis, too, progresses, as a rule, far more slowly than pulmonary phthisis. The cases are never of the foudroyant type. The case, the history of which has been the inception of this discussion, I would class in this group.

To the second class belong the cases resembling croupous and bronchopneumonia. In these cases the process involves lobules, lobes, or even whole lungs. The symptoms are those of a slowly progressing pneumonia. Not preceded, or rarely preceded, by a chill, not accompanied by expectorating of rusty sputum. The temperature is not as high as ordinarily seen in pneumonia. The pulse is not as rapid as in other pneumonias, the respirations are not as frequent, and the dyspnœa is not as great as the extent of the inflammatory process would warrant. The patient is not as sick as in an ordinary case of pneumonia.

The physical signs point to consolidation of the affected area. When, however, the period of crisis, characteristic of a croupous pneumonia comes, there is delayed resolution. This delay which sometimes lasts weeks, and even months. During all of this period there is always a temperature which, while not very high, helps to wear out the strength of the patient. Resolution may occur at any time, and is very much hastened by antispecific treatment. The cases which resemble broncho or lobular pneumonia are apt to show less crepitant and subcrepitant râles than non-syphilitic cases of this type of pneumonia. Here, too, resolution is delayed, and is apt to be incomplete when it does occur, unless the patient is put upon antisyphilitic treatment. In cases belonging to this group, resembling croupous pneumonia, the absence of the diplococcus is an important negative symptom of these cases. Unfortunately, the bacterium causing syphilis being unknown, it is impossible in any of these cases to obtain any positive indications from the sputum as to the presence of syphilis.

The third group of cases, the cases of fibrosis of the lung, associated with gummata of the lungs, stricture of the bronchi, followed by stenosis and atelectasis of lung tissue in the affected areas, will be recognized first of all by their undoubted syphilitic history and the absence of tubercle bacilli in the sputum, for these cases, unlike those in the first group, do not often become the seat of added tuberculous infection, owing to the physical changes which the lung tissue has undergone. These are the lesions which are recognized at autopsy as characteristic of pulmonary syphilis to the naked eye. They are comparatively rare, and it is owing to the fact that the gross changes occurring in the first and second group of cases, while far more frequent, are not so characteristic of syphilis of the lung, but resemble in some respects, on superficial examination, changes produced by tuberculosis, that pulmonary syphilis has been considered a rare complication of the syphilitic disease. The fourth group of cases, while fortunately exceedingly rare, is generally recognized long before the autopsy. The patient is afflicted with gummata in the lung and other tissues adjoining the lungs. These latter, when in the liver, are readily felt, and the physical signs and odor reveal the presence of the abscess cavities in the lungs, these cavities being filled with purulent and decomposing material.

Treatment.—A word as to treatment: The diagnosis having been made, or even a probable diagnosis arrived at from data of the general type of those we have just discussed, together with the existence of a positive syphilitic history, and symptoms of syphilis in other portions of the body; some weight also being given to the absence of tubercle bacilli in some of the cases of the first class, and the absence of the pneumococcus of Fraenkel in some of the cases of the second group; to repeat, a probable diagnosis having thus been arrived at, the patient should be placed upon antisyphilitic treatment.

It is well to remember here, that the success of competent antisyphilitic treatment in cases of pulmonary syphilis will be an important factor in the confirmation of the diagnosis. The treatment, on the other hand, applied in non-syphilitic pulmonary cases, is apt to aggravate the symptoms and course of the disease. The only cases of non-syphilitic origin that could possibly be improved by an iodide and mercurial treatment are cases of simple fibroid phthisis; and in such cases the differentiation might safely rest upon the presence or absence of syphilitic phenomena. I am accustomed to put these patients upon large doses of iodides, beginning with 20 grs. of the iodide of sodium, or 20 drops of the saturated solution of this drug three times a day. I increase by 2 grs. daily to the point of tolerance. Such iodides may be increased to 100 grs. t. i. d. The drug should be given after meals and largely diluted in milk. For 100 grs. a large goblet of milk is required; smaller doses require a wineglassful and upward.

This iodide treatment is combined with the administration of mercury by the mouth, generally $\frac{1}{30}$ of a grain of bichloride, t. i. d., given immediately after the iodide. In addition a drachm of unguent hydrarg. should be rubbed into the skin daily. Nothnagel and Rossbach showed many years ago that the effect of the inunctions of mercury is due to the inhalation of the vapor of mercury, which passes under the clothing of the patient to his mouth, and is inhaled with the inspired air and absorbed through the walls of the bronchi and alveoli.

They did not consider that the mercury was absorbed through the skin in any considerable percentage.

This fact renders the mercury in these pulmonary syphilitic cases of greater and more positive value.

I wish to reiterate again that this communication is intended as a clinical study of a class of cases which I am led to believe, from my personal experience, to be far more frequent than is generally conceded—cases which resemble, clinically, pulmonary tuberculosis, a disease in which the recognized therapy is of uncertain efficacy.

To overlook cases of pulmonary syphilis owing to their clinical resemblance to pulmonary tuberculosis, is an error attended by vast injustice to the individual who is the victim of it. On the other hand, to have mistaken a case of pulmonary tuberculosis and placed it upon antisyphilitic treatment for syphilis, is an error which can be remedied in time when the treatment is found inefficacious. Indeed, ten days of anti-syphilitic treatment will show improvement in the syphilitic cases, and an increase in the cough and other symptoms in the tuberculous cases. If this communication, and others on the same subject, will result in directing the attention of the general physician to the possibility of syphilis as a factor in some of his phthisical cases, so-called, the study of the subject will advance more rapidly, and an important group of cases will be recognized which are now frequently overlooked.

923 Madison Avenue, New York.

THREE PHASES OF PANCREATIC DISEASE, WITH REPORT OF CASES.*

By JOHN H. BLODGETT, Ph.B., M.D.,
SAXTON'S RIVER, VT.

The infrequency of pancreatic disease and the extreme difficulty of making a diagnosis when this organ is affected, makes one reluctant to write or speak upon that subject.

It has been the writer's fortune, good or bad, to have had three cases in the last two years in which post-mortem examination revealed the pancreas involved. A diagnosis of the disease had not been made by the regular medical attendant, or any of the consultants previous to death. The first two cases serve only to remind us that we should have the pancreas in mind when making diagnoses of digestive disturbance; and the third case will help us to differentiate cirrhosis or chronic pancreatitis from cirrhosis of the liver. Before considering these cases, it will be highly proper for us to review the anatomy and physiology of the pancreas.

Anatomy.—The pancreas is situated in the epigastric and left hypochondriac regions. It lies transversely across the body, on a level with the first lumbar vertebra, and is deeply placed. It is of pinkish cream color, and soft in texture. We note three divisions. A head at the right, contained in the loop of the duodenum, behind which, and generally penetrating the same, lies the common bile duct—a fact to be remembered in our later discussion; a middle portion, called the body; and the extreme left of the organ, called the tail.

The duct of the pancreas, or canal of Wirsung, runs from the extreme left of the organ to the right, concealed in the substance of the gland. At the right it either joins or runs beside the common bile duct, to empty into the duodenum. The pancreas lies behind the stomach. Other anatomical facts do not concern us at this time.

Physiology.—The pancreas is a compound racemose gland, weighing about four ounces. It secretes one pint of fluid in twenty-four hours. This fluid has a specific gravity of 1015, and shows, on analysis, about 970 parts of water, 15 of proteids, and 15 of salines to 1,000 parts. The secretion is alkaline.

The proteids represent the ferments, which are four in number: (1) Tripsin; for digestion of proteids. (2) Amylopsin; for conversion of starches into sugars. (3) Steapsin; for the emulsification of fats. (4) Lab ferment; for conversion of casein of milk into peptone, or for precipitation of the same.

---

*Read before the Windham County Medical Society of Vermont.

We note the way this little organ is equipped. It is prepared to do the work of all the other digestive organs put together, and we know, as a result of the progress of surgery in removing the stomach, that this organ will do the work of digestion for months.

A brief résumé of the processes of digestion shows us that some foodstuffs are already in condition for dialysis, others become so when dissolved in the mouth. The uses of the saliva are for the most part physical and mechanical. One ferment, ptyalin of the saliva, has the power of converting starch into soluble substances. Passing to stomach digestion, we find pepsin acting in the presence of free hydrochloric acid for the conversion of proteids into peptones. The power of coagulating the casein of milk must also be mentioned as belonging to the stomach.

Stomach digestion is not considered so important as formerly, and we pass to intestinal digestion as that of greatest moment. To the secretion of the pancreas already described, we must add that of the bile, which emulsifies the fats to a certain extent, and has to do largely with their passage to the lymphatics.

Intestinal secretions come in to assist in the conversion of blood fibrin to peptone, and to change cane to grape sugar. From the small intestine much of the absorption takes place.

Having these facts in mind as a basis for later discussion, we pass to the first phase of our subject, namely:

Pancreatic Disease by Extension.—This case was one of carcinoma of the stomach. There was the usual history of this disease, minus the vomiting and severe pain. Within a day or two of death there was vomiting and some severe pain, which, as with all the pain, was referred to the lower dorsal region, or the left scapula. The late symptoms indicated a beginning peritonitis, with some symptoms of perforation.

Autopsy showed the stomach intact, but walls friable, spongy, and very thick. The disease had extended to the left lobe of the liver. The spleen was involved and the pancreas was matted with the posterior wall of the stomach. The laboratory report was as follows: Stomach shows carcinomatous growth; kidney shows lesion of diffuse nephritis; spleen shows areas of acute degeneration; liver shows diffuse hepatitis, passive hyperæmia, and areas of cirrhosis. The pancreas was not reported upon for some reason. Dr. Lindsey says: "In fact, all the organs show more or less morbid change, although I found evidence of carcinoma only in the stomach."

The patient, in early life, had been an alcoholic. Both stomach and liver suffered, of course, and this was the probable exciting cause of carcinoma. The pancreas also, as we shall see, is an organ that suffers markedly from alcoholism. The report would indicate that the stomach was the first organ affected. The point to be raised here is this, did this man die when the stomach was well nigh incapacitated for digestion, or did he die when the disease had involved the two vital organs of digestion, pancreas and liver? Not until then did we get marked anorexia, flatulency, deep-seated pain, and other digestive disturbance, if our inference is correct. Hence we note the importance of pancreatic disease by extension.

Pancreatic Disease as Part of a General Process.—This patient came under observation a week previous to death, with extreme digestive disturbance, ascites, and œdema of limbs. There were paroxysms of pain, mainly abdominal. There was the gradual wasting and anæmia of malnutrition. Urinary examination showed an advanced chronic nephritis, but the mind was clear. An early history of hip joint inflammation seemed the only important point. The post-mortem examination was a revelation. All the abdominal organs seemed involved, save stomach and intestine. The organs, in gross, looked a brownish-white, something like the rough side of sole leather. In handling an organ, as soon as the capsule was broken it could be crumbled between the fingers. The liver and pancreas were the most involved, and the kidney seemed the last, or, at least, the slowest to break down.

The report of the pathological examination by Dr. Lindsey was as follows:

Liver.—This organ is the seat of a passive hyperæmia or "nutmeg" condition, and there is slight diffuse hepatitis. There is very little connective tissue hyperplasia. There is also a degeneration, which, with ordinary stains, is identical with amyloid change, but this latter cannot be demonstrated with methyl-violet, and gives very faint reaction with iodine. The degeneration is not colloid or fatty, and is believed to be hyaline or amyloid.

Spleen.—A diffuse splenitis is present, and the same degeneration as described above.

Kidney.—Shows much interstitial nephritis and circumscribed areas of round-cell infiltration. The blood vessels are the seat of proliferating endarterites, and the lumina of many of them are entirely occluded. The cortex presents the histological picture of amyloid metamorphosis, but the reaction to staining agents is as described under liver. The glomeruli completely fill the Bowman's capsule, the latter being somewhat thickened.

The pancreas is so far degenerated as not to allow section for satisfactory examination. The gross anatomy was identical with that of other organs. The questions of interest involved here are purely academic, namely:

Did the patient die from the malnutrition caused by degeneration of digestive organs and their accessories, or did life last until the kidney would no longer eliminate sufficient waste to allow continuance of vital processes? Undoubtedly both causes were operative, but the kidney seemingly was the cause of ascites, as there was little connective tissue hyperplasia of the liver. While the pancreas seemed the farthest advanced, the kidney presented, in gross and microscopically, healthy working areas. So much for pancreatic disease as a part of a general process.

Pancreatic Disease, per Se.—The third division of our subject has to do with chronic pancreatitis, as represented in a single case: The patient, a man of about fifty-six years, had been an alcoholic of an extreme type for twenty-five years. Steady drinking was his specialty, with occasional sprees. For the last ten years of his life, at long intervals, he had attacks of deep-seated epigastric pain, very severe, associated with restlessness, anxiety, and faintness. These attacks would compel him, if on the road, to stop at the nearest house until some relief was obtained. There were occasional attacks of jaundice, but not marked. The most marked symptom was a peculiar bronze look to the face, which later, of course, became intermingled with the yellow of chronic jaundice. At the time the patient came under observation he had reached the end of his drinking. A single teaspoonful of alcohol would completely upset digestion and bring on an attack of jaundice.

The digestive symptoms were pronounced at this time, and were anorexia, gastric, and intestinal pain, mainly from gas due to fermentation, pronounced diarrhœa, alternating with constipation; but diarrhœa predominating. The stools were variable in color, for the most part clay-colored.

The digestion went from bad to worse. The urine showed albumin and casts; the jaundice became extreme; the stools colorless; attacks of deep-seated pain frequent. Delirium, followed by coma, resulted from toxæmia, due to absorpton of bile. The patient died in this condition. The diagnosis, by three of the oldest and best practitioners in this county, was cirrhosis of the liver. The cases of cirrhosis of the liver which we have seen fatal, have shown abundant fluid in the abdomen, with œdema of legs, etc. Why was this man dying with cirrhosis of the liver and not a drop of fluid in the abdomen or legs?

Some questions are answered easily at an autopsy, but that was not the case here. We went through organ after organ only to find them practically normal. The intestines even did not show the acute redness which we felt must exist. The liver, to be sure, cut a bit hard on section, but showed only a little increase of fibrous tissue.

Visions of performing an autopsy on a man when sufficient evidence for cause of death could not be found, began to loom up, and our feelings were not soothed by the fact that a brother of the patient, a veterinary to some extent, and a keen man withal, was assisting and observing each step very carefully.

In following up the small intestine, just below the stomach, we came upon a small tumor the size of half a hen's egg and very hard. This was the head of the pancreas, that organ being largely infiltrated with white fibrous tissue. The bile duct, as well as the pancreatic duct, was constricted at this point. The gall-bladder was dilated and filled with bile. The pancreas on sectioning was cut with difficulty. It is to be regretted that specimens of these organs were not sent to the pathological laboratory for examination.

Recalling now the anatomy of the ducts and blood vessels leading to or from the liver, which were cited earlier, we remember that they lie: duct to the right, artery to the left, vein behind and between. The bile duct and the pancreatic duct were constricted by the head of the pancreas while lying in or passing through the same.

The hepatic artery and portal vein were unobstructed, and hence we had no abdominal fluid or œdema. A point then of differential diagnosis between cirrhosis of the liver and that of the pancreas or chronic pancreatitis, if you please, is the question of fluid in the peritoneal cavity.

Chronic pancreatic disease, carcinoma, pernicious anæmia, and chronic liver disease are worthy of our careful study, ante and post mortem, for points of differential diagnosis, because of the marked similarity of symptoms, and the general obscurity of all these diseases. The remark may be made that these diseases are all fatal and a question of diagnosis of very little moment. In reply it is proper to say that in the early treatment a correct diagnosis may be of material service. Public confidence is not increased in the profession when errors are made, and such may be disastrous, from a business standpoint, to the young practitioner. In view of the foregoing facts, is it too much to say that we all may learn something more of pancreatic disease?

While this completes the original plan of my paper, certain considerations of more practical importance may not be out of place at this time.

Each year during the summer months we pass through a time when digestive disturbances prevail. Two years ago a series of, perhaps, twenty cases showed, by chemical and microscopical examination of the urine, a condition of oxaluria, so-called. The symptoms varied—sometimes it was a terrible pain in the head, which called for the hypodermic needle at once; again it would be abdominal, occasionally referred to the stomach, with nausea and vomiting; pronounced constipation was the rule; sometimes there was diarrhœa. Temperature, anorexia, dry skin, scanty high-colored urine, and coated tongue make up the picture. During the acute stage, when the urine was loaded with calcium oxalate, deep lumbar pains, or irritation of the bladder, or both, were pronounced. When this condition, in a subacute form, lasts for any considerable time, we have the dirty, dingy, countenance, the capricious, sensitive, irritable, dull, despondent, and melancholic patient. Boils and other cutaneous disorders follow. It is not difficult to recall such cases—cases in which the nervous symptoms alone are present—and we charge these disorders to faulty innervation, when, as a matter of fact, faulty metabolism is first, nervous dyspepsia, nervous prostration, constipation, and the whole list being secondary, even to acute mania.

A year ago an examination of a similiar series of cases showed uric acid instead of calcium oxalate, and while the majority of symptoms were similar, muscular rheumatism predominated. So far this year the cases seem about equally divided.

The question of metabolism and of accumulated waste products is one of growing importance. What is the matter with me? the patient asks. What is the matter with metabolism? is the real question.

Oxaluria and allied conditions accompany the lighter or severer forms of illness, and has its proximate cause in impeded metamorphosis. Beneke says: "Such a retardation of the metamorphosis of azotized elements of the blood may be determined by the following causes: (1) Excessive use of azotized foods; (2) Excessive use of saccharine and starchy foods; (3) Insufficiency of red blood-corpuscles; causing diminished oxidization; (4) Insufficient access to fresh air; (5) Organic lesions affecting respiration and circulation; (6) Disorders of the nervous system; (7) Excess of alkaline bases in the blood."

Our usual explanation of such faulty metabolism is congestion of the liver, yet we have no jaundice; often no constipation, normal-colored stools showing the secretion of bile normal. May not our trouble be here functional deficiency in pancreatic secretion, quantity or quality? Would not remedies directed toward stimulation of the pancreas accomplish more for us than simple cholagogues?

The Abuse of Creosote and Guaiacol in the Treatment of Phthisis.—Duncan Turner protests against the routine administration of these remedies, which in many cases ruin the digestion and reduce the patient to the very verge of starvation. They are of value in the bronchitis, which is usually present in phthisis, but have no effect on the tuberculous process. Some patients may take moderate doses of creosote and guaiacol for some months without any deleterious effects, but in the larger proportion of cases the continuous administration of these medicines will sooner or later derange digestion and so indirectly do harm. For many years the author has been in the habit of using these remedies through the skin, which is easily accomplished when they are mixed with some kind of oil and diligently rubbed in. He promises a future article on this subject.—*Intercolonial Medical Journal of Australasia.*

THE NEURON THEORY: ITS RELATION TO PHYSICAL AND PSYCHICAL METHODS OF TREATMENT.

By A. D. ROCKWELL, A.M., M.D.,
NEW YORK.

FORMERLY PROFESSOR IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; EX-ELECTROTHERAPEUTIST TO THE WOMAN'S HOSPITAL IN THE STATE OF NEW YORK, ETC.

It is one thing to aid in the resolution of disease; it is another to appreciate the rationale of the means employed. If physical and psychical methods of treatment are to gain in stability and professional confidence, those directly interested in these methods must endeavor to give intelligent expression to the reasons that underlie results. To those directly and experimentally interested, the proofs of the therapeutic properties of such methods are sufficiently convincing, but to those not so directly interested, the iteration of a long list of "local marvels" is apt to become a bit tiresome, and, if not well and satisfactorily authenticated, will be received with a proper measure of credulity. So far as physical methods, and especially electricity, relate to nervous diseases, it will not be disputed that it is in the functional neuroses, so called, that we find their greatest efficacy. Organic and structural diseases receive, as a rule, from their use benefits but slight and palliative, but in such conditions as hysteria, neurasthenia, and many psychical states that have not crossed the border line of insanity, their value cannot be gainsaid. The cause of these beneficial results has, in the past, been referred, in a general way, to nutritional influences, to circulatory and secretory changes, but there has seemed to be no satisfactory anatomical or physiological data to account for the undoubted physical changes necessarily underlying the onset of the nervous symptoms, or to explain the rationale of either physical or psychical methods of treatment. We have now, however, in the neuron doctrine and associated theories, many plausible suggestions as to the rationale of treatment. If, therefore, the neuron theory is correct, if the nerve cell, with its multifarious prolongations, is an anatomical unity, and in association with its fellows by contiguity only, and not by continuity, old ideas of the physiology of nervous activity must undergo very radical changes. I do not forget that more recent researches have distinctly modified the neuron doctrine. The concept of the nerve cell, however, as a functional unit, must still prevail, as affording the most rational basis in the consideration of the action of nerve force. If, in addition to this theory of structural isolation, we accept as true the theory of amœbic movements—in other words, the power of the neuron to swell and retract by means of its protoplasmic prolongations—we get still clearer conceptions of the cause and cure of a multitude of nervous conditions. Doubtless this power of independent movement of the neuron or, what has been termed the retraction theory, has not yet been proven, and may not be susceptible of proof; still, the facts of psychopathology not only render such a physiological process exceedingly probable, but also quite necessary to a satisfactory explanation of mental abnormalities and sudden and transient alterations of sensation and motility.

It has been well said that "theory originally fashions science out of facts, and is the indispensable precondition of every important scientific advance."

Many of the most useful and practical inventions and aids to material progress owe their initiation to theoretical considerations which to this day remain unproved, and yet, as working hypotheses, were absolutely indispensable to scientific advancement. In saying that the central nervous system can no longer be regarded as made up of continuous lines or threads of nervous substance, consisting rather of innumerable units, each one of which is complete in itself and absolutely isolated the one from the other, it is not to be understood that there is no connection between them. This connection is, indeed, most intimate and complex, and may become closer or entirely broken through many causes. All thought processes—the exercise of the passions—fear, joy, hate, sorrow, nervous shock of whatever kind, interfere for either good or evil with this complex system of connections between neuron and neuron. Indeed, the explanation of all mental phenomena, normal and abnormal, resolves itself into a question of connections, and should go far to do away with the term functional by demonstrating that all abnormal functioning of an organ is due to material changes of greater or lesser degree. We say that nervous impulses are transmitted from neuron to neuron through simple contact alone, and that this contact is complete, incomplete, or entirely broken according to the activity of the amœboid movements. These amœboid movements, these retractions of the protoplasmic prolongations of the neuron, whether they be slight or profound, transient or permanent, constitute veritable structural changes, and the difference between a momentary forgetfulness and a permanent amnesia, between a transient paralysis and an incurable hemiplegia, is simply a difference of degree. In either case the nerve impulses are arrested in their course. In the one instance, as in a case of hysterical paralysis, by a defect of contiguity due to slight and transient causes that are readily overcome by some external reinforcement of the nerve wave; in the second by a similar defect of contiguity, due to permanent pressure and destruction of nerve units. Admitting then, that the functional neuroses, as we must still designate them—the hysterias, the neurasthenias—the innumerable grades of abnormal mentality that have not yet crossed the border line separating them from the profoundly or hopelessly insane, are due to amœbic movements of the protoplasmic prolongations, resulting in their retraction and consequent dissociation of neuron from neuron, or, to use a surgical phrase, a practical solution of continuity in the neuron chain, it behooves us to inquire into their causation and into the rationale of the physical and psychical methods of treatment that practically have been found to be of value. An inquiry into the etiology of nervous diseases opens up the whole field of heredity, and the question to what extent one's nervous defects are inherited or acquired are of intense interest, but can be alluded to here only in a general way. An hereditary want of stability of the neuron, with its innumerable protoplasmic extensions, is in the vast majority of cases, without doubt, the fundamental causative factor of abnormal mental phenomena. The majority of neurasthenics who have come under my observation have given an hereditary neuropathic history distinctly bad. When the nervous system of a man hereditarily strong succumbs to the stress and strain of dissipation, or work, or both combined, it is only after repeated and prolonged assaults. The young man rejoicing in a constitution inherently strong makes the great mistake of regarding it as impregnable. It may be a veritable fortress, but nature's reprisals are inevitable, and sooner or later under repeated assaults, it will give way as surely as in the case of his more unfortunate brother with his inherited neurotic instability. Those who belong to the class of the hereditarily weak may, under favoring circumstances, go through life without manifesting serious nervous symptoms, but such cases of exemption are rare.

Every individual must meet conditions that try his mental serenity and test his physical forces, and the nervously unstable rarely emerge from the contest unscathed.

The question of functional nervous disease is very much one of neuron energy. The delicacy and susceptibility of the neuron body must be simply marvelous, yet its vitality is great, and, in vigorous constitutions, it has power not only strongly to resist exhaustive influences, but, even when these influences prevail, has inherent powers of rapid recuperation after the disappearance of the exciting cause. These exciting causes, unquestionably the same in the hereditary and acquired neuroses, are, broadly speaking, two, fatigue and autotoxis. As to the relative importance of these two provocative causes, who can say? Both are accompaniments of civilization, especially the former, and the higher the civilization the greater the ravages of fatigue. There is, moreover, no definite line of demarcation enabling us to say that in this case the results are due to fatigue and in that to autotoxis. Fatigue in itself brings autotoxis, and autotoxis fatigue, but, primarily, the pathologic changes are due to one or the other. It is not alone, nor principally, muscular fatigue from over-exertion, nor mental fatigue from over-intellectual strain, that is meant when speaking of fatigue as the cause of neural disease.

Psychic excitation, when repeated and prolonged, is to the last degree destructive to mental and physical stability. Excessive and long-continued mental effort is undoubtedly responsible for many cases of nervous breakdown. If to this is added the strain of continual worry, the danger is materially increased, but these combined agencies, so inimical to the normal functioning of the pyramidal or psychic cells of the cortex, cannot be compared in deadly energy to the constant impact upon the nerve units of unbridled and unlicensed sexual freedom. As before remarked, all thought processes and all emotional activities disturb for good or evil the functional activity of the psychic cells.

Without such disturbance, indeed, there could be no progression of the intellectual life. "The solitude and the dead-level existence in sparsely-settled rural communities are well-recognized examples of the dwarfing influences of intellectual and emotional stagnation. These depressing environments, while enervating the mental and ethical, tend to quicken and stimulate, as well as pervert, the animal instincts. As a result, crime is more brutal, feuds more revengeful, and for more trifling causes, and insanity more prevalent than in towns and cities." The functional hyperæmia resulting from the exercise of the intellectual forces is a veritable fertilizer, reinforcing the molecular vibration, helping the nutrition of the neuron, and, by increasing the number of contacts of the dendrite with cylinder axis prolongation, developing new paths for the transmission of the nervous current. But let this process be repeated time after time, year in and year out, through unnatural, or at least abnormal, exercise of thought and emotion, malnutrition and exhaustion of the neuron must inevitably follow. The protoplasmic portion of the neuron then retracts (that is the theory), with its resultant solution of physiological continuity, indicating that its vitality is impaired.

As to the toxic origin of nervous diseases, it is becoming more and more evident, through the revelations of physiological chemistry and bacteriology, that it is a most important etiological factor, and a more general recognition of this fact would, I am confident, do much toward the initiation of better therapeutic methods. It may be safely asserted that a large proportion of all aches and pains and abnormal mental phenomena are due directly or indirectly to the imperfectly transformed products of digestion. Mankind is stupid in many directions, but its stupidity in the matter of eating and drinking passes comprehension, and has given rise to the saying that "gluttony kills more people than intemperance." For one cause of insanity or neurasthenia with their profound and varying conditions of mental and physical derangement, there are thousands of cases of transient but ever-recurring disturbances of mind and body due to toxic causes. Man habitually overeats, and the resultant end products cause, by their irritation, a long train of familiar symptoms, heaviness of head, dulness of intellect, vertigo, confusion of ideas, cold extremities, etc. It is not then a cause of surprise that the physiological functions of the body are so frequently disturbed by autoinfection. When one considers the chemical complexity of the human economy, and how tissue metabolism is subject to hindrance and derangement because of disturbed digestive processes, incomplete oxidation, and imperfect elimination of waste material, it is rather a cause of wonder to see how much harmonious action there is in the complicated mechanism of the living body. Our knowledge of autotoxis as a cause of mental and nervous disease is enlarged because of the microscope and physiological chemistry, and it is believed that by urinary analysis the special organ at fault can be designated.

Gastrointestinal intoxication shows itself by the presence of indican, of acetone, of diacetic and oxybutric acids, and of tyrasine in the urine. Hepatic intoxication manifests itself by hemapheisme urobilinuria, albuminuria, renal autointoxication, by the quantity of urine, casts, albuminuria, and hæmoglobinuria. Clinical experience will, I think, confirm the statement that mental and nervous symptoms due to autointoxication differ from those due primarily to fatigue. One of the most striking differences between neurasthenia from fatigue and neurasthenia from autoinfection is the mental confusion characteristic of the latter. It is probable that this confusion of thought is almost universally the result of autointoxication and peculiar to it. How many times, in neurasthenic cases from overstrain, have I seen temporarily this added symptom of confusion, due, unmistakably, to toxic influences. The character of the mental phenomena in toxic and nontoxic neurasthenia differs, according to my experience, in one other important respect. In both forms we find depression and a profound sense of misery, but in the nontoxic form the irritability is not so extreme, nor do we see such unreasonable outbursts of temper as in cases in which the nerve cells are actually poisoned by imperfectly transformed products.

In considering the agencies of autotoxis and fatigue that pervert the normal functioning of the nerve cells, the great susceptibility of the neuron to traumatic agencies should not be forgotten. The persistency and severity of neurasthenic symptoms due to external mechanical agencies are well known and have been widely discussed. Traumatic neurasthenia is expressed in symptoms more profound and lasting than most other forms. The construction of the highly-organized ganglion cells is wondrously complicated and delicate as compared with the cells of the tissues of the body in general. Its metabolism, therefore, suffers especial disturbance from external shock, which, in all probability, leads more readily to actual parenchymatous degeneration than disturbances from fatigue or ordinary toxic causes.

In briefly discussing the rationale of physical and psychical methods of treatment as related to the neuron theory, I shall speak more especially of electricity in referring to the former, both because there is a unique and striking analogy between the nervous and electric conductibility, and for the reason that it is with the action of this agent I am most familiar. In dealing with electricity as a physical agent, I propose also to consider it as a psychical agent, for I am quite free to admit that some of the good derived from electrical methods of treatment are due to psychical influence. No less an authority than Moebius claimed that three-fourths of the cures sequent to electric treatment were due to mental impressions. However this may be, whether the proportion of cures attributed to psychic influences be too large or too small, the fact of its psychical effect is surely no bar to its use.

It is, on the contrary, an additional testimony to its value. Not only every physical method, but the administration of all drugs as well, have their psychical side, and if electricity appeals to the imagination with especial power, so much the better. We know that peripheral stimulation as manifested through the senses, the stimulation of thought, of hearing, of sight, as well as the stimulation born of the emotional elements of our nature, are important forces in the normal development of the psychic cells of the cortex. In equal degree and, perhaps, in the same way, when the function of the neuron becomes impaired, its restoration not infrequently depends in no small measure on those self-same methods of stimulation, sometimes with and sometimes without conscious effort on the part of the patient. I cannot better, if as well, express the importance of psycotherapy in therapeutics, and of the relation to it of electrical methods, than has Dr. Geo. W. Jacoby in his excellent work on electrotherapy. "Let us now only recall two indisputable facts: first, that psychotherapy, no matter in what form applied, may be of benefit in all diseases that have primarily originated through psychic processes; and, secondly, that the action of psychic processes easily oversteps the psychic boundaries and trespasses upon the physical sphere, producing not only functional disturbances, but also structural changes in many organs. In fact, Von Strumpell is right when he says that the number of apparently physical diseases caused by primary psychic processes is at least quite as large as the number of actual primary physical states of disease. Electricity as a purveyor of suggestions is unsurpassed, and I know of no other means by which beneficial results can be obtained with so great certainty and rapidity in affections superinduced by psychic action. If to the psychic action that electricity itself exerts, and to the facility with which it can be made use of as the carrier of intended suggestion, we add its other possible modes of action, we certainly find therein a remedy whose field of influence is not surpassed by any other single method of treatment. These conclusions, theoretically arrived at, stand in full accord with the empirically-acquired knowledge of physicians of the largest practical familiarity with disease and with electric treatment, and who are deserving of credence as scientific observers."

That electricity does possess, aside from its psychic influence, very positive physical effect over diseased conditions will be readily admitted by every unprejudiced mind.

Even Mœbius, whose destructive criticism has, in reality, done much to clear the atmosphere of electrotherapeutics, practically admits that a very respectable proportion of the cures effected by electricity are due to actual physical influences.

The mechanical, chemical, cataphoric, and electrotonic action of electricity are far more in evidence than its psychic or suggestive action. Much of this physical energy is, in truth, mathematically demonstrable, while psychical effects are more a matter of observation and deduction. The influence of electricity on the neuron must be in the main mechanical, or electrotonic, for the action of any of its manifestations upon nerve tissue excites in that nerve a condition of electrotonos, or, in other words, a change in its excitability. To thus influence the protoplasmic portion of the neuron, to heighten its activity and hasten the development of new paths for the transmission of nervous impulses, the surging, vibratory effects of currents of high potential and frequency seem particularly adapted. The greater the number of ties or connections developing out of the protoplasmic body, the richer and more substantial becomes the mentality of the individual. These ties or connections are multiplied and strengthened through emotional (psychical) influences. The natural and incessant molecular vibrations of the nerve elements, thus reinforced by artificial aids, open up new paths of conduction for the transmission of the nervous waves, the obstruction of which give rise to so many symptoms of disease. Whether this molecular influence is exerted through psychical or physical force, it is, in either case, a question of dynamics, the difference being that the dynamics of electricity is far more potential and exact than that of the emotions. The value of physical methods of treatment in the functional neurosis, and even in structural changes, in the hysterias, hysterical anæsthesias and paraplegias, neurasthenias and various mental conditions, has been so frequently demonstrated that illustrative cases seem unnecessary. The rationale of this power lies in great measure, I believe, in its ability to restore the conductibility of the neuron that has become resistant to the nerve current. The inherent energy of the nerve cells is liberated, new paths of conduction form, resulting in modification of both motor and sensory processes.

Disinfection by the Clayton Gas.—A report is given of the results of Dr. Calmette's experiments with a mixture of SO_2 and SO_3 His conclusions are that the gas produced by the apparatus used as is practised in fumigating ships, and of a percentage of 8 per cent., is perfectly efficient for the sterilization of material tainted by the microbes of plague, cholera and typhoid fever. This process assures the destruction of all rats and insects without damage to goods or vessels, and it ought to be generally adopted for the preservation of the health of crews and passengers. He is continuing his experiments on other cultures, and thinks that the gas will prove fatal to the tuberculosis germs.—*Journal of Tropical Medicine.*

SYPHILIS IN THE BARBER SHOP: A CASE OF INFECTION THROUGH AN ACCIDENTAL RAZOR WOUND.

By ANTONIO FANONI, M.D.,
NEW YORK.

The following case is interesting as a contribution to the question as to the acquirement of syphilis through barber's tools—a question that has been the object of considerable study and discussion on the part of sanitarians throughout the world in recent years. Whilst such cases are apparently not very frequent, the mere fact that syphilis may be acquired by almost anyone who ever sits in a barber's chair, is of far-reaching significance. The occurrence of such instances of infection is, in each case, a warning to the medical profession, pointing out its plain duty of furthering legislation that will regulate the hygiene of the barber-shop in such a manner as to prevent the spread of syphilis and of other contagious diseases through the contact of razors, towels, etc., with an abraded surface of skin.

S. F., an Italian fruit-vender, forty years of age, married, with four healthy children, whose family and personal history was negative, except that he had had an attack of gonorrhœa at the age of eighteen, came to me with the following story:

His eldest son, fourteen years of age, on July 28, 1901, shaved him with a razor which the boy had bought "second-hand." Being merely a barber's apprentice, and not skilled in his art, the boy cut his father just below the chin during the operation. The patient did not mind the cut and staunched the bleeding until the shaving had been completed. After a time the bleeding ceased but the wound did not show any disposition to heal. On the contrary, at the end of forty-eight hours the wound seemed to gape and began to discharge a purulent fluid. One of the submaxillary glands, situated about half an inch away from the wound, became enlarged, until it grew to the size of a nut, though it never gave any pain.

A friend of the patient having told him that the wound looked bad, he consulted a physician, who told him that his wound was a very peculiar one, and prescribed some wash, adding that he would like to hear from the patient in a few weeks, regarding any new symptoms that may have developed in the meanwhile.

A month after the wound had been inflicted, the patient went to bed, apparently in perfect health, but awoke in the night with fever, headache, and was unable to sleep. When he arose on the following morning he found that his face and body, except his lower limbs, were covered with a rash. He went to the same physician, who diagnosticated syphilis and prescribed some pills. After a few weeks the rash disappeared, the submaxillary glands diminished in size, and the sore became a little smaller. The medication was discontinued, as the patient was feeling well.

On February 8 he was again seized with headache and sleeplessness, which continued for eight days, and were so troublesome that hypodermic injections of morphine had to be used. It was at this time that the patient came under my observation. I put him on subcutaneous injections of mercuric chloride. After the twelfth daily injection he began to feel relieved, and after the twenty-second he resumed his work, regarding himself in perfect health.

While the case is, undoubtedly, one of syphilitic infection through a razor wound, it is not certain whether it was actually the razor itself that produced the inoculation. It is possible, of course, that the syphilitic virus was introduced into the wound by the handkerchief or some other substance that had come in contact with the cut. The presence of a purulent discharge at the outset indicated a mixed infection, with pus germs as well as with syphilis. The rapidity of onset and the marked reaction accompanying the secondary manifestations of syphilis were, it seems to me, accountable by the fact that the inoculation had taken place through a comparatively large bleeding surface, directly into the systemic circulation. It would be interesting to follow this case through the secondary and tertiary periods, so as to see how marked the syphilitic manifestations will be in future, *i. e.* to determine whether we have to deal with a virulent type of the disease, which is nowadays comparatively rarely seen, or whether the malady tends to run a mild, rather uneventful course under proper treatment, as is often the case with syphilis acquired in the usual way.

The prevention of this form of syphilis insontium is not a problem easy of solution. The disinfection and sterilization of razors and other implements used in the barber-shop are not easy of accomplishment, but the enforcement of even the simplest sanitary measures, and the inspection of barber shops from time to time to secure this enforcement, would go far toward making such unfortunate occurrences as this one very rare, indeed.

119 West Eleventh Street.

Is Sleeping Sickness of the Negroes an Intoxication an Infection?—Hans Ziemann, from his investigations, has come to the conclusion that sleeping sickness is a disease caused by chronic intoxication with a toxic material ingested with the food. The food in question must be a very common one, present everywhere that the negro is, or, at all events, everywhere that the disease exists. Manioc or cassada is, in the author's opinion, the food which fulfils the conditions. It is a fact that it is freely partaken of raw in those countries where sleeping sickness prevails. Properly cooked, it is not poisonous. The disease that at the present time depopulates entire districts of the Congo and Portuguese States may soon disappear by means of the general instruction of the population as to suitable preparation of the root, if the cause of the disease consists in the eating of raw or unsuitably prepared manioc. The question should likewise be investigated as to whether the poison—be it manioc or not—be influenced in intensity by the climatic conditions of the year in question, the telluric influence of the district in question, so that in some years and in some localities the negroes fall ill and in some they do not. The author, in support of his belief that this disease is an intoxication in the same sense as pellagra, and not due to a specific organism, states it as a fact that in the blood of persons suffering from sleeping sickness there is no exciter of disease that can be cultured by the usual methods so as to be made to develop further.—*Centralblatt für Bakteriologie, Parasitenkunde und Infektionskrankheiten.*

The Significance of Abdominal Pain in Typhoid Fever.—Herman B. Allyn cites a number of cases, and insists that pain and tenderness are not necessary accompaniments of typhoid fever; on the contrary, they may be signs denoting the approach or the actual onset of a cholecystitis or perforation of the bowel. Pain is, therefore, a danger signal. It should lead to a more careful study of the case, to more frequent visits, the observations being recorded in writing; and when there is reason to suspect cholecystitis, perforation, or peritonitis, a surgeon should have the opportunity to see the patient early and often. Only in this way can the unfortunate patient with a perforating typhoid ulcer be numbered among the 25 per cent. saved by surgical interference.—*Medicine.*

THE ALLEGED PARASITE OF YELLOW FEVER.

IT was reported last summer that the commission sent by the United States Public Health and Marine-Hospital Service to Vera Cruz to study yellow fever, had found a microorganism in the blood of persons suffering from that disease which was believed to be the long-sought-for causal agent. This news lacked confirmation (we believe the report of the commission has not been published), but the possibility of its truth naturally excited great interest among those who have been making a critical study of yellow fever. In view of this, Dr. Doty, Health Officer of the Port of New York, commissioned Dr. Aristides Agramonte of Havana, formerly of the board of army surgeons under the late Major Walter Reed, whose work demonstrated the agency of the mosquito in the spread of yellow fever, to go to Vera Cruz to investigate the rumor.

In the interesting report of his labors, published in the *Revista de Medicina Tropical* for October, 1902, Dr. Agramonte says that the work of the Marine-Hospital Commission had terminated when he reached Vera Cruz, and he consequently had to look to other but trustworthy sources for data to work upon. The bodies discovered by Dr. Parker of the commission, he says, are seen in blood collected for a study of the malarial parasite and magnified 680 diameters. The supposed parasite is a transparent hyaline body, about half the size of a red corpuscle, to be discovered only on very careful observation. The number of these bodies is variable, but it never equals that of the leucocytes. Some of the bodies are smaller, being only two microns in diameter; none of them is motile, but there is a very evident movement in the protoplasm. Upon examining these bodies attentively one sees that they contain a number of minute granules in rapid motion, three or four coming into sight within the cell and then disappearing together or singly, but never passing beyond the periphery of the hyaline body

The existence of these bodies in the blood of yellow-fever patients was easy to establish, but what relation they bore to the disease was not so readily determined. Dr. Agramonte made a number of experiments in Vera Cruz which gave great probability to the assumption that they bore some causal relation to yellow fever, and at the time of making his report to Dr. Doty he seemed to lean to this belief. In a later communication, however (*Revista Médica Cubana*, October 15, 1902), he says that upon his return to Havana, after having triumphantly demonstrated the "hyaline body" of the Marine-Hospital Commission in the blood of a suspect in Las Animas Hospital, he also found the same corpuscles in the blood of healthy individuals, or at least of those who had not a symptom pointing to yellow fever. He concludes therefore that these bodies cannot be regarded as parasites of yellow fever, although he rejects the suggestion that they are simple blood platelets. They are new bodies, he thinks, which have never before been described, but as to what their significance is he hazards no opinion.

The presence in the blood of minute bodies possessing active Brownian movements is quite commonly observed, and they have repeatedly been mistaken for the parasites of some disease under investigation at the time. Guitéras, who examined the bodies in blood specimens brought by Agramonte from Vera Cruz, thought they were an unusually resistant form of blood-plaques, but whatever they were, they were evidently not yellow-fever germs.

REFLEX ACTION VERSUS AUTOINTOXICATION.

IN the history of thought time was when the "soul" was the *deus ex machina*, the self-motive force of the animal organism which latter existed only to carry out its behests. Following this apotheosis of "consciousness," the nervous system was erected into almost a fetich, and for a century it has been regarded as a tissue apart, a presiding genius, as it were, whose function it is to control, in one way or another, nearly all the functions and activities of the organism. The directive power has been attributed to the ganglion cells as distinguished from the fibers, but of recent years we have found good reason for obliterating this distinction, and for regarding the ganglion cell and the fiber as together constituting a unit, the neurone. And similarly our idea of reflex action has become modified. into the simpler and more scientific conception of a constant streaming of energy from the periphery into, through, and out of the "nervous system,' or, and better, along neurone after neurone, as along' link after link, of the "sensory-motor chain." Those who have observed the trend of physiologic progress during the past decade, and, in particular, those who have read Loeb's "Comparative Physiology of the Brain," and have followed Loeb's later work, will, however, be aware that our comfortable assurance as to our knowledge of the range of function of the nervous system, is in some danger of being disturbed. For not only has Bethe shown that in a crab (*Carcinas mænas*) reflex action persists after destruction of the ganglion cells of the reflex path, but Loeb has shown that in a worm (*Ciona intestinalis*) reflex action persists after the destruction of the entire nervous system, and that here the only function of that system is to secure a more prompt response and a response to a smaller stimulus. A large and increasing amount of data is, moreover, now available tending to show that many functions which would formerly have been unhesitatingly pronounced reflex, are, in reality, if not demonstrably, independent of nervous control, at least capable of explanation by other sufficient causes without reference to it. In other words, the "autointoxication" theory if we broaden the conception to include the action of chemical products normally, as well as those pathologically produced within the organism, is proving itself capable of embracing an ever-widening series of facts. Thus, not only is thyroid secretion absolutely essential to the organism, but the same is true of the secretions, certainly of some, and probably of all, of the other "ductless" glands. Thus the phenomena of Addison's disease and those following extirpation of the suprarenal glands, show that these bodies are indispensable to the maintenance of normal blood pressure and heart tonus. Some, be it noted, formerly referred the symptoms consequent upon extirpation to supposed concomitant lesions of neighboring nerve plexuses, but the action of suprarenal extract complements too closely the symptoms following extirpation for one to believe that its action is other than a chemical one. If it be said that, after all, the lowered plood pressure and the cardiac weakness point to the nervous system, it is none the less the absence of the accustomed specific, nerve-stimulant effect of the extract which causes the failure of the normal innervation. In other words, the action of the suprarenal glands is chemical, through the circulation, and not reflex by stimulation of the nerves ending in them. The latest contribution to this interesting section of physiology is, moreover, fairly unequivocal. Confirming and extending the experiments of Pawlow, of Popielski, and of Wertheimer and Lepage, Bayliss and Starling (*Journal of Physiology*, September 12, 1902), show that the cause of pancreatic secretion is chemical and not nervous; normally the secretion is consequent upon the inflow of the acid products of gastric digestion into the small intestine, and this effect of acid stimulation of the intestine persists after destruction of the spinal cord below the foramen magnum, and of the solar plexus, and after section of the splanchnic and pneumogastric nerves; and it equally follows the injection of acids into a shut-off loop of the jejunum, all the nerves of which have been cut. By special methods they isolated in a state of proximate purity, from the cells of the mucous membrane of the duodenum and jejunum, a substance, "prosecretin," which, by the action of acids, is transformed into the active body, "secretin," which last, on being injected into the circulation, produces secretion in the pancreas. "Secretin" stimulates no other gland, and extracts made by the same process from parts other than the duodenum and jejunum, have no effect upon the pancreas. The interesting question thus arises: Where are discoveries such as these and those made by Loeb likely to stop; in other words, how much will ultimately remain to the nervous system? Any answer to this question would, of course, be premature, but one consideration may be pointed out. Even if this line of research should ultimately go so far as to show that the *chief* function of the nervous system is not the continual adjustment of the relations of the various organs to one another, nevertheless all the neurone groups of the cerebrospinal nervous system would still find their *raison d'être*, and all of them would seem to be necessary, upon the alternative supposition that the function *par excellence* of the nervous system is the stimulation and coordination of those organs whose function it is to effect the continual readjustment of the relations of the organism as a whole to the ever-changing phases of its environment. It is, of course, improbable that the range of function of the nervous system will come to be limited as narrowly as this. Still every extension of the "autointoxication" theory increases the resemblance of the human body to an animal colony, such as a sponge, in which well-marked differentiation of structure and physiological division of labor has taken place, and yet the various parts are able to functionate coordinately, though no nervous system is present. And, certainly, Loeb has shown that physiological law differs less throughout the different orders of the animal kingdom than has been heretofore supposed.

TUBERCULOSIS IN LUNATIC ASYLUMS.

In the MEDICAL RECORD of November 22 editorial comment was made on the report of the Tuberculosis Committee of the Medico-Psychological Association of Great Britain and Ireland, in which it was stated that the charges brought against asylums that tuberculosis was very prevalent in them had been sustantiated. In the same article it was remarked that it would be interesting to find out whether a similar condition of affairs prevailed in the insane hospitals of this country.

The seventh biennial report of the trustees of the Vermont State Hospital for the Insane has been recently issued, and it is gathered from a perusal of this publication that tuberculosis is extremely rife among the patients of that institution. Dr. Walter D. Berry, the medical director and pathologist of the Vermont establishment, in his report refers to the matter in the following words: "In computing the amount of tuberculosis from our autopsies, the percentage has been reckoned as fairly as possible. The common adhesions of the apices of the lungs and pleurisy with or without effusion have not been considered as of tuberculous origin. Those cases which have shown substantial evidence of the existence of the disease have alone been counted. With these ideas in view, the percentage computation figures 31.2 per cent. of tuberculosis found in ninety-three autopsies in this institution." Thus it will be observed that tuberculosis is prevalent in a marked degree in the Vermont State Hospital for the Insane, and it is only reasonable to suppose that a similar state of things exists to a greater or less extent in the institutions of a like nature throughout the United States.

With regard to means of prevention there would seem to be a unanimous sentiment among medical men connected with insane asylums that patients suffering from consumption should be isolated. The fact is now universally recognized that the most effective means of successfully treating tuberculosis is by the open-air treatment, and, both for the sake of those suffering from the disease, and to safeguard those brought into contact with them, isolation and the open-air treatment should be brought into force in all the institutions for the insane in America. Persons suffering from mental affections are notoriously lax and dirty in their personal habits, and, despite the utmost care on the part of nurses, it is impossible to prevent them from performing actions calculated to spread infection among their fellow ward mates.

A practical demonstration of the remarkable results that may be achieved by the rational treatment of consumptive insane patients or convicts has recently been afforded in the case of the New York State prisoners. Superintendent of Prisons Collins has had all consumptive prisoners sent to the State prison at Dannemora in the Adirondacks, the result being that there has been an estimated decrease in the death rate from tuberculosis of 71 per cent in the past five years compared with the five preceding years. As, however, it was pointed out above, insane patients require far more care than those in their right mind, and thus it is incumbent upon the State authorities to deal with these individuals in such a manner that, while they are receiving the best curative and remedial treatment, they should not be allowed to spread the disease.

Dr. Berry and others have been instrumental in inducing the legislature of Vermont to grant an appropriation for a tuberculous pavilion in connection with the Vermont State Hospital for the Insane. It would be to the benefit of the community at large if other States were to follow so excellent an example.

Cancer Research in Great Britain.

Cancer research seems to be progressing apace in England under the auspices of the Royal College of Physicians and Surgeons. Dr. Bashford, who has been appointed Superintendent of the work now being conducted under the direction of these bodies, is making vigorous efforts to get things into good working order. At a meeting of the Executive Committee of the British Cancer Research Fund, recently held, it was announced that Dr. Bashford would proceed at once to Germany to inquire into the methods of investigation at present in force in that country, and to arrange to as great an extent as possible to co-operate with the German commission, especially so far as statistical investigation is concerned.

A feeling has sprung up of late that much of the information obtained with regard to the increase of cancer is by no means reliable, and this doubt has been intensified by the pronouncements of several authorities on the subject, notably by Professor de Bovis of Rheims. Dr. Bashford will therefore endeavor to procure trustworthy data concerning cancer houses, and the effect of diet, soil, and race as agents in the dissemination of the disease. The decision was also come to by the aforesaid committee that the statistical committee recently appointed should forthwith enter into correspondence with scientific workers in the United States. It was stated that Professor Gilman, principal of the Carnegie Fund in Washington, has already expressed his willingness to take joint action with the British committee, in regard to both statistical and laboratory investigation.

When the scientific workers of different nations evince a desire to co-operate in the attempt to solve a problem, the chances are multiplied that a successful issue will be the result. There could not possibly be a better field for such endeavors than that of cancer research. The disease is the most loathsome, deadly, and on the whole the most obscure of all those which afflict civilized man. The discovery of its origin and of curative or remedial measures of treatment would be an unspeakable boon to the entire human race.

Virchow and Evolution.

A short time ago Dr. Frank S. Billings wrote a memoir of the great departed German pathologist. On the whole it was appreciative and critically intelligent. With regard to Virchow's attitude toward the evolution theory—which was one of contemptuous scepticism—the American physician gave as his opinion that it was dictated by envy. The Berlin professor could not brook a peer, or even an equal in the arena of science.

According, however to the *British Medical Journal*, November 15, Mr. Roger Williams of Bristol, England, has sent to that paper a protest, couched in warm and even strong terms, against Dr Billings' interpretation of the meaning of Virchow's bias against the evolution theory.

Mr. Williams opines it to have been due to a defect in the constitution of his brain He writes as follows "As is well known Virchow had a deeply-rooted constitutional aversion to all kinds of theories and hypotheses. He credited nothing that could not be definitely proved This lack of scientific imagination was no doubt due to defect in the original constitution of his brain. Had he been better gifted in this respect, he would certainly have been not merely the greatest pathologist of the nineteenth century, but the greatest of all time. On account of this defect Virchow must be assigned a place in the scientific hierarchy distinctly below that occupied by such men as Cowle, Spencer, and Darwin. Thus may be explained Virchow's well-known opposition to the principle brought to light by modern biological progress as exemplified by the doctrine of evolution. Another consideration that tended to confirm him in this opposition was the fact that in the domain of pathology, where his ideas concentered, evolutional conceptions seemed to have but little application, for most pathological phenomena are the outcome of the failure or undoing of evolution."

Virchow, the writer in the *British Medical Journal* pithily says, would probably, if he could revisit the pale glimpses of the moon, prefer to dispense with the help of a champion like Mr. Williams, who vindicates his character at the expense of his intellect. He might well say: *Non tali auxilio nec defensoribus istis.*

Overproduction of Weaklings.

There is at the present time an English writer of fiction who works with considerable trained scientific knowledge, an infinite ingenuity in construction of plot, and an imagination of the most vivid and of the highest order.

This writer, Mr. H. G. Wells, has recently been turning the light of his intellect upon anthropological and social problems, and has contributed a series of articles which are appearing in the *Cosmopolitan.* In the November number of that magazine he deals with the question of over-population, and the deterioration of the human race under the present conditions of life in civilized countries. With regard to infant mortality, Mr. Wells is especially eloquent, and his strictures on things as they are are pungently scathing. He says, in part, "A portion of infant and child mortality represents, no doubt, the lingering and wasteful removal from this world of beings with inherent defects, beings who, for the most part, ought never to have been born, and need not have been born under conditions of greater foresight. These, however, are the merest small fraction of our infant mortality. It leaves entirely untouched the fact that a vast multitude of children of untainted blood and good mental and moral possibilities—as many, perhaps, as one hundred in each one thousand born—die yearly through lack of sufficient food, lack of sufficient good air, and lack of sufficient attention. The plain and simple truth is that they are born needlessly. There are still far too many births for our civilization to look after adequately; we are still unfit to be trusted with a rising birth-rate "

Mr. Wells's remedy for this state of affairs while no doubt Utopian at the present juncture, is, nevertheless, based upon some solid foundation of common sense The first of the expedients "he thinks" which would lead to a permanent improvement in these matters, is the establishment of a minimum of soundness and sanitary convenience in houses, below which standard it shall be illegal to inhabit a house at all. There should be a certain relation between the size of rooms and their ventilating appliances, a certain minimum of lighting, certain conditions of open space about the house, and sane rules about foundations and materials. These regulations would vary with the local density of population. Legislation against overcrowding is another measure recommended by the writer.

Of course, space is wanting to refer more than cursorily to some of the features of the article, and the matter was only mentioned to show that the interest now taken in questions of this kind is widespread. Mr. Wells's views have received much attention at the hands of English medical men, and it is recognized that he has treated the subject in a brilliant and, in many respects, in an illuminating manner.

Alcoholism.

The London *Practitioner*, November, is devoted to a discussion by various well-known English authorities, upon the ever-burning alcohol question. The writers of the numerous articles treat the subject from many points of view, the result being that a valuable and instructive set of articles is got together.

With regard to alcohol as a beverage, of course all the contributors are unanimous in declaring that excess is distinctly harmful, and that there can be no gainsaying the fact that strong drink,taken in large quantities or frequently, is injurious in a high degree, but some of the writers strongly contend that alcohol, taken even in moderate quantities, is both unnecessary and very prejudicial to health.

Sir Samuel Wilks, however, thinks that it is a most valuable remedy, and if so, necessarily must do harm when injudiciously given. As regards the value of wine or alcohol as diet, he says, "This is an interesting question from a physiological point of view, but of no practical importance, being outside medical practice, as the masses of people in all countries never consult the doctor on the subject."

From a sociological standpoint, nothing but condemnation can be passed upon the alcohol habit, for distinguished men, from every class of life, are as one in insisting that it is responsible for most of the crime, vice, poverty, and misery which exists so widely in all civilized countries.

The weight of authoritative opinion nowadays veers toward the view, that alcohol has little or no value as a diet, although be it said, there are still some who vigorously combat this statement.

Dr. Sims Woodhead, who represents the purely scientific phrase of the matter among the contributors to the *Practitioner's* symposium, is a stout opponent of the vaunted use of alcohol as a medicine, and will allow but few merits to it as a therapeutic agent.

Mr. Pearce Gould takes a similar stand, and thinks that there is no greater fallacy than that alcohol is of any use in infectious diseases. He further gives as his opinion that to those suffering from cancer alcohol is absolutely pernicious. In cases of shock, he says that it is useful in tiding over an emergency.

The change of opinion with respect to alcohol in medicine among the medical profession has been nothing less than remarkable. It is not many years ago since alcohol was regarded by the majority of medical men as, in certain conditions, one of the most effective remedies known. Now, to many it is anathema marantha.

The present situation, with regard to the manner in which alcohol is looked upon by the greater number of prominent members of the medical profession in different parts of the world, may be fairly stated as follows. As a medicine, its value is more or less open to question. With regard to its dietetic qualities, these are so greatly counterbalanced by its undoubted injurious properties, that the great mass of the human race would be the better mentally and physically if stimulating drinks were partaken of sparingly or entirely avoided.

Infant Mortality in Liverpool.

The Liverpool correspondent of the *Lancet*, writing in that journal in its issue of November 15, refers to the infantile mortality and the reduced birth rate in the city. Dr. E. W. Hope, the medical officer of health of Liverpool, in his annual report for 1901, drew attention to the reduced birth rate of the city, which had fallen from 38.6 per 1.000 in 1877 to 32.2 per 1,000 in 1901. In the part of Liverpool known as the Scotland division, 222 children out of every 1,000 born died before twelve months of age. In the Sefton-Park district, 120 died.

In the course of an inquiry into the causes of infantile mortality, 1,082 families, in which the death of an infant occurrred, were taken consecutively, and certain particulars concerning them were ascertained. The total number of children born in these families had been 4,574, but out of that number 2,229 had died, practically all in infancy, representing 487 deaths out of every 1,000 born, a waste of life nearly five times as great as the standard generally regarded as unavoidable. But the most remarkable series of excessive fatality occurred in twelve families, in which the large total of 117 infants had been born, and no less than ninety-eight had perished in infancy. These extreme examples occurred in families in which, as far as municipal sanitation was concerned, there was very little to choose between them and many of the families who reared all, or nearly all, their children; nor could it be shown or inferred that there was any inherent weakness in the offspring, since those who had survived were of fair physique, and not, as a class, suffering under any inherited condition likely to terminate their lives. It was in the personal and domestic circumstances that the contrasts were more marked. Want of proper feeding was responsible for a large proportion of the deaths of the infants. A careful investigation had been made into the circumstances of upward of 1,000 consecutive deaths in districts where infantile mortality was excessive. In 21 per cent. the families were described as exceptionally dirty, in 18 per cent. the mothers went out to work, leaving the infants in the custody of others, frequently in the custody of another child, who could give the infant no proper attention; about 11 per cent. of the total were living in dwellings unfit for human habitation. In upward of 25 per cent.—and these were the cases in which the mortality appeared to be highest—the parents were markedly intemperate.

Liverpool is a typical British business town, in which the sanitary arrangements are effective, the water supply good, and fairly plentiful—where, in short, the municipality takes good care of its citizens' health, so far as it is able. The point of the matter is, that most of this solicitude avails but little, if the personal and domestic habits of the people are insanitary. When parents neglect their children, feed them injudiciously, and allow them to exist amongst filth and vice, the result must be that there will be a large infantile mortality. The only remedy would seem to be education.

News of the Week

Moral Influence of the Army Canteen.—Paymaster-General Bates has submitted a report to the Secretary of War, saying that the claim of the War Department that during the operation of the canteen in the army discipline was superior, desertions less, and trials by court-martial on account of breaches of military discipline resulting from the use of intoxicants fewer is fully borne out by the records of the office of the Paymaster-General. These records show that during the year ending June 30, 1902, when there was no army canteen, the amount collected in fines and forfeitures from 70,000 regular enlisted men exceeded by over $150,000 that collected from 75,000 during the last year the canteen was in existence. Commenting on this General Bates says that "this increase cannot be attributed to any other cause than the effects of an uncontrolled liquor traffic, in connection with military posts, which traffic appears to seriously affect the discipline and morale of the army."

New Superintendent at Bellevue.—Dr. William Mabon, at present medical superintendent of the St. Lawrence Hospital for the Insane at Ogdensburg, has accepted the superintendency of Bellevue Hospital. He will take charge of Bellevue and the allied hospitals on January 1, and will also act as consulting physician to the pavilion for the insane at Bellevue. Dr. Mabon was graduated from the Bellevue Hospital Medical College in 1881.

Coroner's Physicians.—The Board of Coroners last week appointed Dr. Otto H. Schultze Coroner's physician to succeed Dr. Hamilton Williams, who resigned some time ago. He will be Coroner Brown's physician. His name headed the eligible list. The board also confirmed the appointments of Drs. O'Hanlon and Higgins, who had been retained by Coroners Jackson and Goldenkranz when they came into office. Coroner's physician Weston will be retained by Coroner Scholer. The action of the Board in taking Dr. Schultze from the eligible list practically means that the coroners have abandoned the struggle to make the position exempt.

A Scholarship for Study of the Thymus.—Mr. Mason of Oxfordshire has established, under the direction of the Royal College of Physicians of Edinburgh, a scholarship to the annual value of £200, tenable for two or three years for original research into the diseases of the thymus and other ductless glands. The first holder of the scholarship is Dr. Swale Vincent, who will work under the direction of Professor Shäfer of the University of Edinburgh.

An Orthopedic Hospital for Chicago.—It is reported that Dr. Friedrich Müller, the assistant of Dr. Lorenz, who accompanied him to this country to reduce the congenitally luxated hips of a daughter of J. O. Armour, will return to Chicago soon and engage in the practice of orthopedic surgery. Mr. Armour will, it is said, establish and endow a memorial orthopedic hospital to be under Dr. Müller's direction, if the operation performed upon his daughter is successful in its results.

Bad Reports from Havana.—A report on the sanitary condition of Havana has been made to the State Department by the Secretary of the American Legation in that city, in which it is said that a relaxation of the sanitary system introduced by the American military authorities is gradually but surely taking place. Santiago and several others of the Cuban cities are said to have already fallen back into their pristine state of filth, and if Havana now follows suit, it is only a question of time when the old pestiferous conditions will return.

The Suppression of Osculation.—Dr. R. B. Ware of Lowesville, Va., has introduced into the Virginia Legislature, *quorum pars magna est*, a bill to limit the practice of kissing to those of sound lungs and healthy frames. The bill would make it a misdemeanor, punishable by a fine of from one to five dollars for any person to kiss another, unless it can be proved, by the testimony of the family physician, that the osculators are free from all infectious disease, as well as from pulmonary trouble. The wording of the bill would seem to restrict the prohibition to the male sex, but it was doubtless the intention of the framer to include kissee as well as kisser.

College of Physicians of Philadelphia—At a stated meeting, held December 3, Dr. John H. Gibbon read a paper entitled "Gangrenous Cholecystitis, with Report of a Case in Which Cholecystectomy Was Successfully Performed." He exhibited the enlarged gall-bladder, with greatly thickened walls, and also a calculus of considerable size that was contained in the viscus. Drs. David L. Edsall, J. B. Wile, and C. B. Fife presented a communication entitled "A Study of Urobilinuria and of Some of the Toxic Excretory Products in Pregnancy and the Puerperium." They found, contrary to the previous statement of an Italian investigator, that urobilinuria was not a physiologic manifestation of pregnancy and the puerperal state, being found present in some and absent in others of a considerable number of such cases investigated. The condition was, however, found associated with intestinal decomposition, and was attributed to changes in the bile in the intestine, brought about as a result of bacterial activity. Drs. David Riesman and A. C. Wood read a paper entitled "A Case of Gangrene of the Lung Cured by Operation," and Dr. G. E. Pfahler exhibited skiagraphs showing the conditions prior and subsequent to the operation. The gangrene was supposed to have developed in the sequence of lobar pneumonia.

Philadelphia Hospital.—The Association of Ex-resident and Resident Physicians of the Philadelphia Hospital held its sixteenth annual banquet at the Hotel Bellevue, Philadelphia, on December 2, with some eighty participants. The following toasts were responded to: "The Future of Blockley," by Dr. John V. Shoemaker, President of the Department of Charities and Correction; "The Past and Present of Blockley," by Mr. Wm. T. McLaughlin, a member of the Department of Charities and Correction; 'Blockley Rats," by Dr. John H. Jamar of Elkton, Md.; "The Resident Staff," by Dr. Morris Tyndall; "Olla Podrida," by Dr. James B. Walker. Remarks were made also by Drs. John K. Lineweaver of Columbia, Pa., Theodore Diller of Pittsburg, Pa., Jas. P. Tuttle of New York, Roland G. Curtin and G. E. Pfahler. The following officers were elected for the ensuing year: *President*, Dr. E. L. Duer; *First Vice-President*, Dr. H. C. Wood, *Second Vice-President*, Dr. John K. Lineweaver; *Secretary*, Dr. E. R. Stone.

A Sudden Thought and Its Serious Consequences.—A man named Parmenter, who was a healer of the Eddyites, dropped dead in the street in this city a few days ago. His claim was certainly a strong one to induce him to pass on so rapidly.

A Popular Handbook on Consumption.—It is announced that Drs. Hillier of England and Koch of Germany will collaborate in the compilation of a popular treatise on tuberculosis and its prevention.

In view of his peculiar views on the relation of bovine to human tuberculosis, Dr. Koch can hardly be regarded as a safe leader in the crusade against consumption. Dr. Knopf's work on "Tuberculosis as a Disease of the Masses, and How to Combat It," which received the prize of the International Congress on Tuberculosis, is assuredly a far more trustworthy guide than one embodying Koch's theories.

The Paris Academy of Medicine.—On November 25 the new building of the Academy of Medicine of Paris was opened with appropriate ceremonies. The building is in the Rue Bonaparte, adjacent to the Ecole des Beaux-Arts.

The Fourth Pan-American Medical Congress.—The Government of the Argentine Republic has requested the executive committee of the Fourth Pan-American Medical Congress to postpone the meeting from June, 1903, the date originally agreed upon, to October, 1905. The reasons given for the desired postponement are the inability of the local committee in Buenos Ayres to make their preparations for a worthy celebration of the congress on the earlier date, and also the fact that the Fourteenth International Congress at Madrid, coming at the end of April, would dwarf the Pan-American, if the latter were held in June of the same year.

Pan-American Sanitary Conference.—The first international sanitary conference of the American republics convened in Washington on December 2, and continued three days. The governments of Mexico, Cuba, Chili, Costa Rica, Salvador, Honduras and the United States were represented by the delegates. The conference was the outgrowth of an international meeting held a year ago in the City of Mexico. Many subjects relating to quarantine and public health were discussed, and several resolutions were adopted. One of these, offered by Arthur R. Reynolds of Chicago, urged the different governments to study in their respective territories the geographical distribution of the mosquito, in order that it may have practical application in subsequent conventions. A resolution, offered by Dr. Guitéras of Havana, was that measures of prophylaxis against yellow fever should be based upon the fact that up to the present time the bite of certain mosquitos was the only proven natural means of the propagation of yellow fever; and that the governments represented in the conference should approve the measures employed in Havana for the prevention of the spread of the disease on land, for the isolation of cases, and the fumigation of buildings. The resolution further provided that the prevention of the importation of the disease by vessels wherein persons actually infected are found, must conform to the methods employed on land, but it was admitted that there were questions concerning the importation of infected mosquitos that required further study before any decided modification of the quarantine laws can be recommended. The resolution provided that the subject of bringing the quarantine laws to conform with the new doctrine of mosquito infection shall be referred to the International Sanitary Bureau of the American Republics for a report at the next meeting. A resolution pertaining to the work of the International Sanitary Bureau, whose permanent headquarters are to be at Washington, was adopted by the conference. It makes it the duty of the bureau to urge all the parties represented in the conference to transmit promptly and regularly to the bureau all data of every character relative to the sanitary condition of their respective ports and territories; to furnish the bureau every opportunity and aid for thorough, careful, and scientific study and investigation of outbreaks of pestilential diseases occurring in the territories of the republics; requires the bureau to lend its aid and experience toward the widest possible protection of the public health of each of the republics, in order that diseases may be eliminated and commerce facilitated; and also to encourage and aid or enforce in all proper ways the sanitation of seaports, including the sanitary improvements of harbors, sewerage, drainage of the soil, paving, elimination of infection from buildings, and the destruction of mosquitos and other vermin. Dr. Charles Wardell Stiles of the Department of Agriculture read a paper on ankylostomiasis, in which he held that the degeneracy of the "poor whites" in the South was the direct result of this condition. It was decided that the next conference meet in Santiago de Chile, March 15, 1904.

A Filtration Plant Suggested for New York.—The question of filtering the water supply derived from the Croton water shed, which was much agitated a few years ago, has been revived by a committee on typhoid-fever prophylaxis of the German Medical Society of this city. The committee has sent a letter to the Mayor, the Board of Health, and the Aqueduct Commissioners suggesting precautions against typhoid fever. It is asserted in this letter that many cases of the disease in this city result from impure Croton water, and the committee urges that the city construct a filtering plant, and predicts that good filtration would reduce the number of typhoid fever cases in New York by one-half and save hundreds of lives. Attention is called to the fact that the populous Croton water-shed is liable to all sorts of unavoidable contaminations, and that the only remedy for such a condition is filtration of the water before it reaches the consumer. The morbidity rate for typhoid fever has been greatly reduced in all cities where filtration plants have been installed.

Obituary Notes.—Dr. Timothy Field Allen, long one of the leading homœopathic practitioners in New York, died on December 5, following an apoplectic stroke received about a year ago. Dr. Allen was born at Westminster, Vt., in 1837, and was graduated from Amherst College in 1858. From that college he also received the degree of A.M. in 1859 and the degree of LL.D. in 1885. He was graduated from the New York University Medical School in 1861. In 1862 he was acting assistant surgeon in the army. Besides his medical work, Dr. Allen made a study of botany and published several books on that subject. He was a charter member of the New York Botanical Garden.

Dr. Levi J. Hixson of La Salle, N. Y., died on December 5, as the result of an overdose of cocaine. He was a graduate of Trinity Medical College, Toronto, in the class of 1888.

Dr. Daniel Pearsons Pease of this city died of typhoid fever in Paris on December 7, at the age of forty-six years. His illness attacked him while he was at Antwerp on a pleasure trip with friends. He went to Geneva, thinking to recuperate there, but returned to Paris as soon as he discovered the nature of his illness. He was born at Chicopee, Mass., and was graduated from the Bellevue Hospital Medical College in 1882. For a time he was connected with the Charity Hospital, and then besame resident physician on North Brother Island. He had an extensive practice in New York, being the physician of three large and fashionable hotels, besides having a large clientele among the permanent residents of the city.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

CROONIAN LECTURES—KING'S COLLEGE—SUPRAPUBIC CYSTOTOMY IN TUMORS OF THE BLADDER—REDUPLICATION OF THE FIRST SOUND OF THE HEART—CLINICAL FEATURES OF AN EPIDEMIC OF DOUBTFUL ORIGIN.

London, November 21, 1902.

There is a note of sadness about the delivery of the Croonian lectures this year. They were intrusted to the late Dr. Washbourn, whose death I reported to you. He had written them out in the rough before his decease, selecting the natural history and pathology of pneumonia as his subject. The revision of his MS. was undertaken by Dr. J. W. H. Eyre. Another colleague, Dr. T. G. Stevens, had contributed illustrations. Dr. W. Hale White yesterday completed the task he had undertaken in this kindly commemoration of Washbourn, viz., reading the lectures before the Royal College of Physicians.

King's College bids fair to get the half million she asked for. A meeting was held to support her claims on Wednesday, when the Bishop of London read a message of sympathy from the King. He also announced that he hoped, in conjunction with the Bishop of Rochester, to endow the Faculty of Theology, out of some church funds with at least £1,500 a year. Sir R. Jebb, Sir Wolfe Barry, Sir Douglas Fox, Sir A. W. Rücker, Sir John Cockburn, Colonel Legge, M.P., Mr. A. Gibbs, M.P., and Mr. W. F. D. Smith, M.P., representing other departments put in special pleas for them, and the Earl of Selborne, who presided, testified to the value of the work done by the college to advance learning and science in general, and mentioned the many opportunities he had had when under-secretary for the colonies of observing the excellent work of her alumni in various parts of the empire.

A paper on "Suprapubic Cystotomy in Vesical Tumors" was read by Mr. Lockwood at the Royal Medical and Chirurgical Societies. A study of his own cases, and of those operated on at St. Bartholomew's Hospital from 1891 to 1900, led him to conclude that an ideal operation should fulfil the following conditions: (1) Early endoscopic diagnosis; (2) asepsis before, during and after operation; (3) excision of the tumor, together with its base, and a safety margin of healthy tissue; (4) closure of the wound left by the excision; and (5) closure of the suprapubic wound.

Mr. Lockwood referred to the different results produced by calculating according to the numbers of patients or the number of operations. In fifty-three operations at St. Bartholomew's upon thirty-seven patients, only thirty-two had one operation; two had two operations; two had four, and one had nine. Of the thirty-two single operations, in sixteen the growth was removed and in sixteen it was irremovable; of the former cases three died; of the the latter, seven; the chief causes being shock, hemorrhage, and sepsis. When the urine is septic and the tumor irremovable, the operation would seem to be useless and fatal.

Mr. Reginald Harrison dwelt on the risk of sepsis, which he thought mostly due to imperfect drainage. He thought catheter drainage of little use, and an independent perineal wound safer.

Mr. Hurry Fenwick had operated on 153 cases out of 500 he had seen, with only eleven deaths, and he urged that a careful selection of cases would reduce the mortality. The selection must be by the endoscope. A tumor that could be felt *per rectum* should not be interfered with; it was almost certainly malignant.

Mr. Lockwood, in reply, objected to perineal drainage as a probable source of sepsis. When cases could be operated on early enough, much of the risk of sepsis was avoided. He agreed with the importance of the endoscope—especially if the urine contained blood.

Another paper at this meeting was by Dr. Phear on reduplicated first sound, which might, he thought, be associated with cardiac disease, chiefly mitral regurgitation; arterial disease, due to strain, lead poisoning, or renal trouble; pulmonary lesions, mostly emphysema, with or without bronchitis; anæmia, chiefly of chlorotic type; dyspepsia. Out of 109 cases there were only nine of arterial disease, with albuminuria, showing that it was of less significance than supposed as an indication of granular kidney.

Dr. Seymour Taylor said a double first sound alone did not indicate disease, though when attended by a double second sound, it might.

Dr. Alex. Morison also held that a double first sound might be present in a state of perfect health, and could not be indicative of serious disease. He had often seen it follow a change of posture.

The causation of the reduplication was differently explained by the speakers, but it seemed to be generally thought due to a synchronism of the two sides of the heart

A rather unusual epidemic broke out suddenly in Lincoln in the early part of last May, and the clinical features observed were described by Dr. W. H B Brook, at the Clinical Society of London, on Friday last. The most striking features were sore throat with œdema, the tonsils in many cases being covered with a drab-colored fur; in two-thirds of the cases a dark, measly eruption appeared on the second day, and lasted sometimes a few hours, and in other cases about a week, showing a tendency in some instances to return as late as the sixth week; in some cases it resembled urticaria. Desquamation occurred in about a third of the cases. The fever was generally under 102° F., unless there were complications, the pulse was not increased in proportion. Seventy-five cases were observed, nearly all in adults. The most common complication was swelling of the cervical glands about the fourth day, with high temperature, and in some cases this came on after full recovery, and was attributed to a too early return to meat diet, which also produced a tendency to gastritis. Stiffness of muscles and joints occurred in some cases, in one so severe as to resemble rheumatic fever, the stiffness persisting for several months. Septic phlebitis occurred in one case, aged sixty-six years, and was fatal on the twentieth day. With one doubtful exception, all the patients had milk from the same dairy, which was suggestive of the point of infection. Dr. Klein invested the epidemic and isolated a microbe. The best treatment seemed a rest in bed on a milk diet. Calomel was usually given at first, followed by a saline and salicylate of sodium, later on quinine. Nitrate of silver to the throat, and a gargle of carbolic acid and borax, gave relief.

Dr. Goodall said such epidemics in other places had been traced to milk, and added that in scarlet fever there were often curious eruptions.

Dr. Goffe asked if Koplik's spots had been looked for, and the usual sequelæ of scarlet fever.

Dr. Savill said the symptoms were similar to those observed in the 1891 epidemic in the Metropolitan infirmaries. He believed that the poison was conveyed by milk. He said that a tendency to skin diseases was noticed in the London infirmaries every autumn.

Mr. J. R Lunn had observed several similar outbreaks, which he thought were due to milk, and lately he had met with two or three isolated cases which made him apprehensive of another.

In his reply, Dr. Brooks said boiling the milk was a preventive. Koplik's spots were looked for in every case; but never found. Antistreptococcic serum was used with great effect, reducing the temperature at once from 105 to 100° F. There were cases of true scarlet fever during the epidemic, and the difference was marked.

OUR PARIS LETTER.

(From Our Special Correspondent.)

MEDICAL INSTRUCTION IN ITALY—DR. JOSIAS'S STATISTICS IN THE TREATMENT OF DIPHTHERIA—BROCA'S REPORT ON THE TREATMENT OF APPENDICITIS—SAVARIAUD'S ARTICLE ON THE SAME SUBJECT—LAWS VOTED BY ITALIAN PARLIAMENT RELATING TO INTERMITTENT FEVER—REMOVAL OF TWO TUMORS OF THE BREAST BY AN INCISION MADE IN THE AXILLARY REGION—THE NEWSPAPER CAMPAIGN AGAINST SOME PARIS HOSPITALS.

Paris, November 24, 1902.

Medical instruction in Italy is, according to Gottschalk, furnished by seventeen different universities; the great number of these is due to the former division of Italy into a number of small States. These universities are found in Bologna, Cagliari, Catania, Genoa, Macerata, Messina, Modena, Naples, Padua, Palermo, Parma, Pavia, Pisa, Rome, Sassari, Sienna, and Turin. There is also in Florence an institute which is equivalent to a university. There are also four independent universities at Camerino, Ferrara, Perugia, and Urbin. There is, however, no medical school at Macerata. There are about 6,000 medical students, of whom a third are to be found in Naples, which is also much frequented on account of the obstetrical work that is furnished. The medical instruction lasts six years, and there are nineteen different examinations, and two special ones on subjects chosen by the candidate. The cost of tuition is 800 francs in all.

The finances of the last year in France have not been very encouraging, and an increase in the taxes could not be readily carried out. There is some discussion going on as to the advisability of making the sale of alcohol a monopoly under the direction of the State, such as exists in Russia. This would be an easy method for increasing the revenue of the State. In Russia only 100,000,000 roubles were obtained in this manner in 1866, whereas the amount obtained now is 300,000,000. It would, however, hardly be wise to increase the revenue of the State by favoring drunkenness, and recent accounts from Russia seem to indicate that such is the case there.

At a recent meeting of the Académie de Médecine, Dr. Josias of the new Bretonneau Hospital for Children gave his statistics for diphtheria during 1901–1902. During this year 580 children afflicted with diphtheria, recognized by means of bacteriology, were admitted to his service. Out of this number seventy-six died, which is a mortality of 13.10 per cent. From this number, eighteen should be subtracted, as having been brought in a desperate condition to the hospital. The mortality is, therefore, only 10 per cent. Bronchial pneumonia seems to be the chief cause of death, and should be avoided by strict antisepsis. Such statistics show that there has been a steady improvement, which is due to the use of the serum. Before it was employed the mortality was at times as high as 48 or 50 per cent.; in 1894 it fell to 21 per cent., and nowadays it is only 10 per cent. Even better results might be obtained by carrying out the injections sooner, and by injecting children who have been exposed.

The treatment of appendicitis is still discussed as much as ever, and a comparison between Broca's report at the Congress of Surgery, held at Brussels, and Savariaud's article on the treatment of appendicitis shows how different are the opinions held by French surgeons. Still Broca's ideas on the subject seem to be accepted by most surgeons, and even Tuffier made no remark after his report. Broca compared the immediate or urgent operation to the operation simply deferred, and gave the results he had obtained in his hospital service. Formerly, he used to operate immediately, and during the three years running from 1892 to 1895 the percentage of deaths was 33, or 26 deaths out of seventy-nine cases.

Seven cases were not operated upon, and ended in recovery; eight were operated *à froid*, and were discharged cured; lastly, sixty-four were operated on, *à chaud*, and twenty-six died. In 1896 the mortality fell to 13.33 per cent., in 1897, 1898, and 1899 there were only ten deaths out of ninety-two operations, which is 10.86 per cent. Since this period the mortality has remained at 10 per cent. According to Dieulafoy's statement, one should never die of appendicitis, and if the patients were sooner in the hands of the surgeon, there would be fewer deaths, not so much on account of the operation, but because the medical treatment is often pernicious in its effect. It can hardly be said that the statistics have improved on account of increased technical skill, as Rimussoir, who employed the radical treatment for just one year rapidly came back to conservative treatment, as he had 50 per cent. of mortality. The chief course of such heavy mortality is that by breaking down the adhesions, when seeking the pus, one is apt to infect the whole peritoneal cavity. Even if the mortality were the same, there is this advantage about the deferred operation that one can much more readily look for the appendix and remove it, and it is not so necessary to drain and cause fistulæ or hernia. These objections could hardly be raised if the patient were operated upon at the very beginning of his illness. But two or three days are generally lost by the family and the physician. There is one fact to be remembered, which is that it is well to wait quite a long time when there has been much puffiness of the part affected.

Savariaud's article is written in a different spirit, and in it he speaks of the danger of temporizing, due to septicæmia or toxæmia. Then it should be remembered that once cured of his attack of appendicitis, the patient may not desire to be operated upon, and once the pain is gone, it will be hard to get the patient to consent to an operation. On the other hand, arguments such as possible errors of diagnosis, inoculation of the peritoneum, difficulty of removing the appendix at this time, and danger of subsequent hernia are easily laid aside.

Savariaud said that in some cases it was not necessary to leave the incision completely open, but that a small orifice was quite sufficient in certain forms in which there was not as yet any pus. He had never regretted operating on appendicitis, and he had once been misled as to the gravity of an appendicitis, with the result that when the operation was performed, general peritonitis was found. Savariaud considers that theoretically the safest treatment of appendicitis is an immediate operation, with removal of the appendix. In his practice he does not always carry out this principle, when, for instance, the diagnosis is not certain, when the appendicitis is slight and the symptoms are disappearing, or when the operation could not be carried out with the usual precautions. In surgery it is hardly wise to admit but one form of treatment, as exceptions to a general rule are sure to be found.

The Italian Parliament has just voted two new laws aimed at the suppression of intermittent fever, which are certainly excellent. According to the first law, when a peasant is taken with fever while at work, he will be furnished with quinine and will be taken care of at the expense of the proprietor who is employing him. An attack of intermittent fever is considered as an accident taking place while at work, and the proprietor should insure himself against such risks. The other law fixes the maximum price of quinine, and when there are no druggists in a place this drug will be sold at the shops having a monopoly of salt and tobacco, and the revenue obtained thereby used to stamp out intermittent fever.

Dr. Morestin, a young hospital surgeon, has reported recently two cases of tumor of the breast, which he operated upon by making an incision in the axilla, and thereby avoiding a visible scar. In one case the incision was 6 cm. long, and the skin was detached by means of a scalpel, until the breast was reached, and the tumor was removed through the tunnel thus made. The breast had been pushed toward the axilla during the operation. In the second case the incision was only 3 cm. long.

A drain was placed in the wound and removed forty-eight hours after.

The Paris papers have been publishing reports recently to show how wretched some of the hospitals are as to their condition, and state of repair. An article was published yesterday in which a description of the old Hôtel Dieu Annexe is given, with its dead house down in the cellar, its sagging ceilings and generally insalubrious condition. A maternity is established in one of the wings, and there is only one bath tub for the whole establishment. The lying-in ward is quite small, and the isolation of infected patients is necessarily incomplete. When this hospital is compared with the Boucicaut Hospital, one is struck with the enormous difference that exists between the old-time institution, destined for the very poor, and the modern establishment, that receives all sorts of patients. A large sum is to be spent in transforming some of the hospitals, and a loan is to be negotiated for this. The hospital of La Pitié, which dates from 1613, will most likely be torn down and replaced by modern buildings.

A NEW PHASE OF PROFESSIONAL ADVERTISING.

To the Editor of the Medical Record:

Sir: For many weeks past and since a distinguished Austrian orthopedist visited this country to perform "a most miraculous operation" on one of our citizens, I have been wondering what can be the real limit of advertising professional work.

The good professor would naturally say that he is not to blame for what others do, and he may be ignorant of the bad impression he is making upon his professional brethren, but nevertheless he has evidently taken no active pains to disabuse the public mind of the conviction that he is the one and the only one who can work the alleged miracle. Worst of all, it seems to be generally understood by the public that nothing of the kind has been done before and that the entire profession of America is at the feet of this new orthopedic apostle. What seems also as passing strange is that our leading orthopedists who have heretofore been considered discerning individuals and competent to judge high professional qualifications in their own line are more than eager to follow in the trail of this senseless public advertising. But for such credit as can be rightly claimed for American orthopedy, I, even as one not directly interested in the specialty in question, feel bound to protest against the implied assumption that our own surgeons are not the equals if not superiors of any in the world; those of Austria not excepted. I fail to see why it seemed necessary for the profession in Chicago, St. Louis, and other cities to be so eager to learn how properly to reduce a congenitally dislocated hip and keep it there long enough for the head of the femur to burrow a socket for itself.

It gives one a tired feeling to realize how much of profitable advertising has been missed for many greater achievements by a want of knowledge of the newer foreign methods.

In the face of all this hurrah we are apt to lose sight of the fact that this wonderful operation was performed years ago by American surgeons who thought no more of this precedure than to report it as an ordinary one and certainly not as one that required the gifted touch of genius to make it successful.

I do not say that it is not a good thing to relieve the cripples, to hold free clinics for the public and gather them in "for the sake of stimulating subscriptions to hospital funds," but even these good intentions have their limits for sober thought and dignified action.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Dec. 4, 1902.

A Note on Pleurisy in Typhoid Fever.—George G. Sears calls attention to the probable fact that pleurisy resulting from infection with Eberth's bacillus is less rare than commonly supposed, being overlooked because it simulates so-called idiopathic pleurisy. It is, however, a rare complication on the whole. Betke found fifty-eight instances among 1,420 cases. It occurs most usually after the first week, when the temperature is still high, but it may be delayed until convalescence seems fully established, or even occur as a complication of a relapse. Usually its onset is insidious, and its presence is discovered only on physical examination. Etiologically, Eberth's bacillus has been demonstrated as the cause in a considerable proportion of cases. None of the initial cases ended fatally, while a large proportion of the later ones died. None, however, which came on before the twelfth day were either hemorrhagic or purulent. A serous effusion seemed to add but little to the gravity of the original disease, while two of seven in which it was hemorrhagic, and six of eighteen in which it was purulent, died. Free incision and drainage of an empyema was usually required, yet a few recovered after repeated aspiration, with or without the injection of antiseptics.

Some Observations upon the Value of the Phloridzin Test for Estimating the Functional Capacity of the Kidneys; Renal Sufficiency.—Francis S. Watson concludes from his observations: That the average quantity of sugar eliminated in the first half-hour after the administration of the drug subcutaneously in certain doses and when the kidneys are normal, is about .45 per cent., and that the first half-hour's elimination is greater than the second half-hour's by about .06 per cent. When renal disease exists, the first half hour's quantity of sugar eliminated is, for a series of cases, about one-half as much as that when the kidneys are normal, and there is but little more in the first half hour than in the second. When the kidneys are normal, ether anæsthesia stimulates them to greater activity, but, judged by the phloridzin test, the renal function is not impaired by the anæsthesia. When the kidneys are impaired, ether fails to stimulate their function, and there is relatively less sugar eliminated in the first than in the second half hour after phloridzin has been given than when the kidneys are sound. Judged by the average results of a series of cases, the phloridzin test gives accurate indications of the condition of the renal function and of the existence of renal disease. In a certain number of cases it even appears to be more delicate and discriminating than the ordinary urinary tests, but other numerous instances, which show the reverse of this to be true, show it to be too variable to be trustworthy. Therefore the author does not urge its adoption in preference to the former methods of urinary analysis for estimating the functional capacity of the kidneys.

Journal of the American Medical Association, Dec. 6, 1902.

The Treatment of Tuberculous Glands of the Neck.—From a general consideration of the subject, Leonard Freman comes to the following conclusions: (1) The gravity of tuberculosis of the cervical lymphatics, as regards both local deformity and remote secondary manifestations, is generally underestimated. (2) General treatment, especially hygiene, is of the utmost importance, both in the cure of incipient trouble and in the prevention of relapses following operations on more advanced cases, most recurrences being due to neglect of such measures. (3) Residence at the seashore has long been recognized as of great benefit; but there is reason to believe that a high and dry climate, such as that of Colorado, with its rarified, stimulating atmosphere and abundant sunshine, possesses superior advantages. (4) A point of extreme importance in local treatment is to abolish sources of infection, in the teeth, tonsils, nose, ear, scalp, etc., and neglect of this is apt to result in failure. (5) Non-operative treatment is often of doubtful utility, except in the beginning of the disease. (6) Pulmonary involvement does not contraindicate operation, at least in Colorado, except in advanced cases. (7) Curettage is applicable to sinuses, tubercular ulcers of the skin, and where complete removal would be attended by too much risk. In all other instances a thorough operation should be done. (8) The size and shape of the incision should be adapted to the particular case. It should be free enough to permit of thoroughness and safety. (9) The chance of permanent cure following operation is probably better in Colorado than in lower and less favorable altitudes.

The Microscope in the Diagnosis of Scarlet Fever.—W. K. Jaques describes a variety of a germ resembling at first glance staphylococcus albus, but differing from it in many particulars. These are so peculiar that it is difficult to place it in any definite class of bacteria. It is very sensitive to environment, and is modified in form so it may appear as a diplococcus, a streptococcus, or a streptobacillus, merging from one to the other in the same culture. Only by studying many cultures can one appreciate this variation in form. It also has a wide variation in size—from a point which can just be distinguished with an oil immersion twelfth to (in old cultures) a coccus a third the diameter of a red corpuscle. The multiplication is by division, and it multiplies in all of its varying sizes. Because of its minute form it can penetrate almost any tissue of the human body. The shape, as usually seen, is round with what appears to be a hole in the center. This is due to refraction or to staining qualities. As a germ increases in size a dividing line may be seen in the center. In the older cultures, in which the coccus is large, on each side of this center line the cell substance stains in the shape of a crescent with the points toward the line. It is very susceptible to environment, and is often seen to assume the streptococcus form or to become egg-shaped and sometimes almost a bacillus. Jaques's four years' study of the class diplococcus may be summed up as follows. If a child has never had scarlet fever and the clinical symptoms are present (such as characteristic angina, vomiting, delirium, and high temperature) a rapidly-growing culture of the class coccus from such a case determines the presence of scarlet fever, while its absence excludes the disease. In some cases the culture has decided the nature of the disease before the rash was observed, the patient isolated, and others protected. In other cases when the rash was present, but the clinical symptoms obscure, the absence of the class coccus decided the case as not scarlet fever. In mixed infection, when germs of scarlet fever and diphtheria are both present, the microscope is of life-saving importance, as the more prominent symptoms of scarlet fever may obscure those of diphtheria.

Medical News, December 6, 1902.

A Comparative Study of the Value of Methylene Blue and Quinine in the Treatment of Malarial Fever.—John T. Moore and W. L. Allison present their conclusions on this subject, which do not differ materially from those of Thayer and others who have used methylene blue. (1) Methylene blue will destroy malarial parasites in many cases, but is less certain than quinine. (2) Methylene blue is probably most valuable in chronic cases, but has no advantage over quinine. (3) The effects of methylene blue are ordinarily more unpleasant than quinine. (4) It is useful in cases that cannot take quinine on account of some idiosyncrasy to it. Its use in cases of pregnancy is undetermined. (5) It is probably valuable in treating hæmoglobinuric fevers on account of its diuretic action; this has yet to be determined. The writers have had no chance to test its use in such cases. (6) They believe that quinine is quicker and much more certain, and would rely upon it rather than upon methylene blue.

New York Medical Journal, December 6, 1902.

The Treatment of Vascular Neoplasms by the Injection of Water at a High Temperature.—The tumors thus treated by J. A. Wyeth have been arterial, capillary, and venous angiomata. Boiling water is injected directly from a cauldron under strict antisepsis. The quantity varies with the size of the tumor. At times the temperature of the water need not be over 190° F. It should be hot enough to coagulate the blood and the albuminoids of the tissues, but it should not be hot enough or under such pressure as to scald and cause necrosis of the skin. The operation is to be performed under complete narcosis. In no instance has any painful symptom or septic reaction ensued, with the exception of a single case in which a superficial eschar formed. Suppuration ensued, but the beneficial results of the treatment were the same as in the other cases.

A Case of Cancer of the Larynx Cured by the X-Rays.—The patient of W. Scheppegrell was a man of fifty-seven years with an involvement of the left wall of the larynx, affecting also the corresponding cord. For the first three weeks after daily ten-minute exposures the result was discouraging. After the twentieth exposure treatment was discontinued for a while, but examination a few weeks later showed a vast improvement. Treatment was again resumed. Six months later the larynx was in good condition and the case considered cured. No mention is made of removal of a portion of the growth for microscopical examination. The author expresses firm belief in the correctness of the diagnosis and believes the case to be the first on record of a cure of malignant disease of the larynx by the *x*-ray.

American Medicine, December 6, 1902.

The Modern Treatment of Eclampsia.—Herbert Marion Stowe gives the following principles of treatment for eclampsia at term: (1) Control the convulsions; (2) Deep narcosis should be induced during all pelvic manipulations; (3) There must be rigid antisepsis in all pelvic manipulations; (4) Remedies that will control the toxic effect should be administered; (5) Stimulate immediately all the excretory organs; (6) Empty the uterus by the most natural method possible without undue regard for the life of the child, especially if the condition of the child is poor; (7) Dilution of the toxins floating in the body fluids is necessary; (8) Stimulate the vital centers when necessary.

The Relation of Oxaluria to Glycosuria.—Frieda E. Lippert has made a protracted series of urinalyses in urines supposedly diabetic. There were in nearly all the cases the familiar clinical pictures of that disease. But tests failed to show the presence of sugar. Although prolonged boiling is directed to be avoided, the writer tried the effect of from fifteen to twenty-five minutes of boiling after adding the urine to the test solution. The test tube then stood for twelve or eighteen hours afterward. A copper-colored sediment appeared. There was microscopic evidence of abundant oxalates. The writer thinks that it is probable that the yellow precipitate was indicative of oxalates in an abnormal degree. And the suggestion arose that the oxaluric state might be a precursor of the glycosuric state that it so nearly resembled. She believes that there is a very definite relation between oxaluria and the diabetic condition. The line of research must in future be to establish the measure of it. If it be fundamental, there is an added means of clinical diagnosis at hand. If it be only coincidental, there is at least a field wide in its resources for clinical variation.

Pus in the Pelvis Depending upon and Complicating Appendical Disease in Women; Methods of Treatment.—John B. Deaver states that a localized purulent collection in the female pelvis may be due to a pyosalpinx, tuboovarian abscess, suppurating ovarian cyst, suppurating fibroid, hæmatocele, or appendical disease. Appendicitis may cause a pelvic abscess in one of three ways: (1) By the extension of a purulent collection from the right iliac fossa to the pelvis; (2) By an appendical abscess in the pelvis, with the appendix hanging over the ileopectineal line or entirely in the true pelvis; (3) By infection of the tube and ovary with involvement of both appendix and adnexa in a purulent exudate. The treatment of the appendical abscess will depend upon the location of the pus and the condition of the patient. If the patient's condition is desperate, the abscess may be evacuated by drawing the cervix well forward or backward. The posterior vaginal wall is then incised freely, either anteriorly or posteriorly, the peritoneum is opened and the pus evacuated. Irrigation is contraindicated and the cavity is simply drained with gauze.

Philadelphia Medical Journal, December 6, 1902.

The Symptoms of Prostatic Hypertrophy, Their Cause and Their Relief.—Edward L. Keyes, Jr., briefly sums up his opinions on this subject as follows: (1) Chronic obstruction to urination is the underlying cause of almost all the symptoms attributable to hypertrophy of the prostate gland; (2) This obstruction may be regarded as an elevation of the internal orifice of the urethra; (3) Yet obstruction may exist without symptoms, and symptoms without obstruction; (4) For the immediate cause of all the symptoms is congestion; (5) Hence to the patient the disease represents only a congestion; (6) While to the surgeon it represents, for the most part, an obstruction, an elevation of the urethral orifice; (7) The symptoms may often be relieved by relief of the congestion without regard to the obstruction; (8) Yet such treatment is purely palliative and is not the function of an operation; (9) Radical treatment consists in permanent relief of the obstruction in the floor of the urethra, with little regard to congestion; (10) This may be accomplished by cauterization or extirpation of the offending mass through a perineal or a suprapubic incision; (11) The operation to be preferred must attack the obstacle most directly, and remove it most rapidly, while preventing hemorrhage and providing perfect drainage; (12) Of the operations employed at the present day, the one which most often fulfils these conditions is perineal galvanoprostatotomy. The writer speaks of the technique of the operation as follows: Through a median perineal incision the bladder is entered, and the finger explores the urethral obstruction. Then the galvanocautery instrument is introduced, and with it incisions are burned through the neck of the bladder and the prostate, each incision being made with the sole purpose of lowering the neck of the bladder. Thus, if a simple contractured neck is found, a single incision, 1 cm. long, divides it. A massive enlargement of the gland is attacked by one or two incisions into the lower part of the bladder neck. A single or double lateral hypertrophy, with no appreciable median enlargement, is attacked either by incising through the middle of the obstructing lobe or by cutting away its attachments from the bar of mucous membrane at the bladder neck. A hypertrophied median lobe is either split or freed with an incision at each side of its base, after which it may be easily torn away and removed. If the surgeon judges the growth too great for perineal extirpation, he has lost only a few minutes and may proceed to suprapublic section.

The Lancet, November 29, 1902.

A Curious Case of Lead Poisoning in an Infant.—H. C. Cadman reports the case of an infant of five weeks with colic and constipation. He was treated in the usual way with partial benefit, when it was discovered that the mother had been wearing a lead shield over the nipple. The action of the shield on the milk was practically to form lactate of lead. The infant's urine responded to the bichromate of potash and other tests for lead. Proper hygienic measures brought the case to a successful termination.

A Case of Scarlet Fever Followed by an Interesting Relapse.—The patient of H. Fraser was twenty years old. The disease ran the usual course, and the patient was up on the thirteenth day, desquamating in the usual manner. Six days later a severe diarrhœa and vomiting came on, and in a few hours a pronounced punctate rash appeared, which, by the next morning, had involved the whole body, except the face. Three days later the rash was fading. The course of the disease was thereafter without incident. Fraser gives two possible theories as regards the origin of the relapse or second attack: (1) That it was simply an instance of autointoxication in a patient whose immunity was short-lived (author's belief); (2) that a fresh strain of the poison was contracted by the patient on getting up.

A Case of Fulminating Appendicitis with General Septic Peritonitis: Operation; Recovery.—J. H. Evans reports the case of a boy aged four years, operated on forty-eight hours after invasion. Twenty hours later, the condition of the patient was bad in the extreme, there being vomiting of coffee-ground material. Drainage tubes, previously inserted, were removed, and the wound opened up throughout. The appendix removed at operation was found to be perforated, and containing a mass larger than a cherry stone, on the proximal side of which a fig-seed was found. During the first few hours after operation a saline enema brought away hard, scybalous masses. Recovery, after the reopening of the wound, was uneventful. According to the author, the points calling for explanation are (1) the obstruction of the fig seed; (2) the formation of the enterolith; (3) the cause of the perforation and fulmination; (4) the thrombosis of the vessels, and (5) the scybala which were passed per rectum. 1. As to the obstruction, eight days prior to the attack the child had eaten some stewed figs, from which the seed, which was found, had evidently come, and this produced a certain amount of obstruction to the exit of the natural secretion of the epithelium. 2. This irritation, associated with microorganisms, produced inflammatory changes, which, in the eariler stage of hyperæmia, brought about the increased secretory activity and multiplication of the epithelial cells, resulting in the formation of the enterolith. 3 and 4. The irritants, increasing the morbid process, led to an extensive involvement of all the submucous, intramuscular, and perivascular subserous lymphatic channels, culminating in an acute endophlebitis and consequent gangrene, which was more marked at the point furthest removed from the mesenteriolum where the perforation—probably accelerated by the pressure of the enterolith—was found. 5. The scybala, which are invariably passed a few days after the attack by those patients who recover from acute appendicitis have been considered by some eminent authorities as the "offending particles"; but in the writer's opinion they are nothing more than the usual fæces deprived of their fluidity while in the sigmoid flexure.

British Medical Journal, November 29, 1902.

Two Cases of Consumption Probably Infected by Tuberculous Milk.—James M. Cowie reports these cases. They were a boy of seventeen years and his sister of five years. Neither of these patients drank much milk, but the milk supplied to them was almost continuously tuberculous for over two years. Specimens of the milk were examined and proved to be infected. In both of these cases the disease began in the abdomen. In the case of the girl it never reached the lungs, while in the boy the lungs were affected secondarily. No other source of infection but the milk could be found in either case.

"Slow Continuous Fever."—R. V. Dolbey states that during the campaign in South Africa at least four different cases of sickness with temperature were classified under this heading. Apart from cases of fever in the malarial district and the recrudescence of malaria in soldiers, he has noticed the following types: (1) Cases with temperature from 99° to 102°, which almost always last three days, and are generally accompanied by diarrhœa, and always with headache, chilliness, and general weakness. Rest in bed and fever diet is the treatment required. This fever oftens occurs after exposure. (2) Cases with temperature from 100° to 102° or 103°, with severe pain in lumbar region and thighs, often severe headache, and generally diarrhœa; the temperature falls in a series of cases on the seventh day. Sodium salicylate is given with great benefit (3) Cases with temperature from 100° to even 104°, with headache, vomiting, and irregular pains. Constipation is the rule; sometimes pea-soup stools are found. They resolve in about fourteen days. They are probably fourteen-day typhoid cases. (4) Cases beginning with rigor, and which eventually resolve themselves into ordinary cases of enteric. Fever is often irregular and constipation is the rule. There are many cases of cardiac failure, without any apparent sign on auscultation previously. Pleurisy and other lung complications often occur.

Dyspepsia and Its Treatment by Antiseptics.—Guthrie Rankin declares that dyspepsia may be acute or chronic. The latter may be classified as atonic, acid, or nervous. The same general symptoms are found more or less in all cases, but their combinations are numerous. Many of them are undoubtedly dependent upon the production and absorption of poisons. Atonic dyspepsia is the most common form of chronic indigestion and occurs in persons who are badly nourished. It is more frequent in women than in men. Acid dyspepsia occurs most often in strong, active men, and is associated with an undue amount of hydrochloric acid. The nervous form depends upon nerve exhaustion and occurs in neurotic individuals. As to treatment, in acute dyspepsia there can be but little diversity in our methods of managing it. Rest and removal of the stomach contents will bring about a cure. In chronic dyspepsia the cause must first be determined. All violations of the laws of health must be set right. No two cases can be dieted alike. Simple, nourishing, and easily-digested food should be ordered. The writer has found carbolic acid to be the best of all the antiseptics he has used. In atonic dyspepsia, great relief is obtained in most cases from a combination of dilute hydrochloric acid, pure carbolic acid, strychnine, and ginger. The following formula is given: Dilute hydrochloric acid, 15 minims; pur carbolic acid, 2 grs.; solution of strychnine, 5 minims; tincture of ginger, 20 minims; glycerine, $\frac{1}{2}$ drachm. This is best given diluted with water about an hour after the principal meals. In the acid type of this disorder, alkalies are especially indicated, given two or three hours after food. Bismuth is most useful. In nervous dyspepsia, the writer likes the following formula: Zinc valerianate, 3 grs.; pure carbolic acid, 2 grs.; arsenious acid, $\frac{1}{40}$ gr.; extract of cannabis indica, $\frac{1}{4}$ gr. One capsule should be taken after food three times a day. Mental and physical rest in this form of dyspepsia is imperative.

Hair-Balls and Other Concretions in the Stomach.—W. Soltau Fenwick states that certain concretions are apt to form in the stomach and to give rise to severe abdominal symptoms, accompanied by abdominal tumor. They consist generally of hair, cotton, wool, or string, but occasionally entirely of vegetable fiber or resinous material. Hair-balls large enough to attract attention are very rare, and only about twenty-four cases are recorded in the literature. When rather small, the mass is round or oval and occupies the pyloric region, where it acts like a ball-valve. As it grows in size, it is moulded by the contractions of the stomach until it forms a solid cast of the organ, and may even extend into the œsophagus, or through the pylorus. It is smooth, compact, and heavy. Out of the twenty-four cases of patients with hair-balls, that are on record, twenty-three were females, the youngest being eighteen and the oldest thirty-four years at the time of death. In most of the cases, the habit of swallowing hair originates in the trick of holding the hair in the mouth while reading a book or of biting the ends in anger or excitement. In every case there is a well-marked tumor. The duration of the disease is not easy to determine, but probably averages about fifteen years. Vegetable tumors are far less common than the preceding, and, as a rule, consist of fruit-skins, fruit-stones, and stalks, or of the fibrous roots of certain medicinal plants. The subjects of gastroliths are usually men about middle age, who have taken varnish, polish, or any resinous fluid containing alcohol. Concretions are accompanied for some time by symptoms of dyspepsia, and seldom prove fatal in less than ten years. When a concretion gives rise to a palpable tumor but without gastric symptoms, it is most likely to be confused with an enlarged spleen, a floating kidney, or with a fecal accumulation in the colon. If the tumor is small, it may possibly be removed by an emetic, but there is some danger in this, as there is often secondary ulceration of the stomach or duodenum. If the tumor is large, medicinal treatment is useless and only gastrotomy will avail.

Deutsche medicinische Wochenscrift, November 13, 1902

Immunization with Diphtheria Bacilli.—A. Lipstein, similarly as A. Wasserman, has obtained a specific agglutinating and bacteriolytic serum by the inoculation of diphtheria bacilli. The technic employed was essentially the same as that used by Wasserman. It does not appear that the value of this serum for the differentiation of true and false diphtheria bacilli is as great as is supposed by the latter author. While such a serum, in high dilution, agglutinates and destroys the same diphtheria bacilli by the means of which it was produced, it does not have such a marked action upon other true diphtheria organisms—in some instances, in high dilution, not agglutinating them at all. It is probable that this variation in agglutinative power is due to the variety and multiplicity of receptors present in the bodies of various diphtheria bacilli. It is possible that this drawback may be overcome by the production of a polyvalent serum similar to that now obtained with the streptococcus. Work is now in progress along this line.

Cholelithiasis and Diseases of the Pancreas.—Paul Fuchs thinks that the close anatomical relations between the bile passages and the ductus Wirsungianus is evidence that diseases of the former are prominent etiological factors in affections of the pancreas. If the bile-ducts are enlarged, pressure is produced upon the ductus Wirsungianus, and the pancreatic secretion is dammed back upon that gland. This leads to congestion of the pancreas, with all its consequences. Much observation has shown that such conditions as pancreatic abscess and acute hemorrhagic pancreatitis are, as a rule, associated with diseases of the gall-bladder or ducts. It is also possible that the reverse may occur, and that diseases of the pancreas may be causative of cholelithiasis. In certain cases it is impossible to say from the autopsy findings which has been the primary lesion, but in most cases it is clear that cholelithiasis antedates the pancreatic condition. At all events, in the treatment of suspected or definite pathological lesions of the pancreas, early attention should be given to the condition of the gall-bladder and ducts.

Munchener medicinische Wochenschrift, Nov. 18, 1902.

Hetol in the Treatment of Tuberculosis.—Hermann Riegner reports the treatment of twenty-one cases of pulmonary tuberculosis with hetol, a preparation of sodium and cinnamic acid. While no cures were obtained, there was in all a marked improvement in the general condition and local symptoms, so that it is evident in the treatment of phthisis that the effects of this drug are not to be underestimated. By far the best results were obtained when it was given intravenously. Administration by other methods did not seem to be of much avail. In each case during the course of treatment from 30 to 50 such intravenous injections were given. No unfavorable symptoms ever developed as the result of the injections. In none of the cases was any other medication given during the course of treatment.

The So-called "Hardening" of Children.—Hecker is outspoken in his objections to the methods pursued in the so-called "hardening" of children by the means of cold douches or baths. As a rule, children thus treated are more susceptible to nasal catarrhs, throat affections, bronchitis, and pulmonary inflammations than those who have not been subjected to the "hardening" process. Furthermore, such measures frequently give rise to pronounced anæmia and various disorders of the nervous system. Children so "hardened" are especially prone to acute and chronic intestinal disorders While in healthy children a properly conducted "hardening" process is often of advantage, it must be remembered that there are no hard and fast rules, and that every case must be treated according to the individual indications The fundamental principles of a proper "hardening" system are as follows: (1) Gradual acclimation to the air of the room; (2) Gradual acclimation to out-door air, (3) Gradual acclimation to cold water; (4) Suitable clothing—varied according to the weather and time of year. Great care should be observed in acclimating the child to cold water, and the effects of the same should be carefully watched, the endeavors being at once suspended on the first appearance of any unfavorable symptoms. On no account should any of the "hardening" measures be commenced until the nursing period is passed, and in all cases the process should be one of gradual advancement.

French Journals.

Cutaneous and Pupillary Reflexes and Visceral Sensation of Diabetics.—Pitres states that the following results have been obtained from examinations made in the case of thirty-two diabetics: The cutaneous, abdominal, cremasteric, and plantar reflexes were abolished more frequently than the patellar reflex, which was discovered to be abolished in 40 per cent. of the cases. On the contrary, the reflexes of the pupil to light and accommodation were normal, and the Argyll-Robertson pupil was never found. The epigastric and testicular sensations, abolished in tabes, were intact in the diabetic. These different points can serve in the diagnosis of diabetic pseudotabes.—*Journal de Médecine de Bordeaux*, November 16, 1902

Aneurysm of the Heart.—Mollard and de Bernard de Teyssier describe this case. The heart was taken from a patient who had died from cancer of the rectum. There was a large aneurysm in the cardiac apex. There had been no appreciable sign of this lesion during life. It was, in fact, an aneurysm resulting from an infarct of the myocardium. The anterior coronary artery was very atheromatous and obliterated toward its middle part. It is surprising, according to these observers, that such a lesion should remain latent, and that, in the antecedents of the patient, there was no cardiac incident corresponding to the formation of the infarct. This latency can, perhaps, be explained by the poverty of the apex of the heart in nerve cells. Indeed, there are scarcely more in this region than nerve terminals.—*Lyon Médical*, November 16, 1902.

Nocturnal Incontinence of Urine; Liberation of the Meatus; Recovery.—A. Malherbe had under his care a young woman of twenty-seven years, who had suffered from nocturnal incontinence of urine for twenty years. After some months of medical treatment with no result, she demanded an operation. Two incisions were made from the clitoris toward the vagina, and the superior and inferior angles of each incision were sutured together, so that each vertical incision was transformed into a horizontal incision, and the meatus strongly brought up. This last result was favored by a transverse incision made under the meatus. After the operation there was no incontinence for eight days. Then there was a return of the trouble for three months. The administration of strychnine was begun. Little by little the trouble ceased, till, finally, it entirely disappeared.—*Le Progrès Médical*, November 15, 1902.

Gastropathies and Enteropathies of Static Origin.—Gaston Lyon, in his very interesting paper, speaks of the benefits of massage in cases of ptosis. In recent cases in which the vertical dislocation is alone concerned, massage seems to have an indisputable curative influence; in old and complicated cases, it always gives relief. It exercises a mechanical action in favoring evacuaton of the stomach; besides this, a trophic action in reviving the tonicity of the gastric musculature. In cases in which the subpyloric sagging is considerable, and if alimentary stasis exists, lavage of the stomach can be practised. However, its repeated usage will cause rapid denutrition. Forced feeding has a double influence: local, by encouraging increase of fat—especially abdominal fat, which strengthens the tension of the abdomen; general, in increasing the strength, and, consequently, influencing the nervous system.—*Gazette des Hôpitaux*, November 13, 1902.

The American Journal of the Medical Sciences, Nov. 1902.

Osteitis Deformans and Hyperostosis Cranii; a Contribution to Their Pathology, with a Report of Cases.—Morton Prince concludes that: (1) We have no sure ground for differentiating hyperostosis cranii from osteitis deformans. (2) Hyperostosis cranii and osteitis deformans are probably trophic disorders. (3) Various clinical and pathological facts seem to indicate that they are at least allied disorders, and perhaps only different manifestations of one and the same disease. (4) The osteoarthritic changes so commonly found in osteitis deformans are probably manifestations of the disease, and not complications. (5) The results of autopsies thus far made do not at all exclude the nervous system as the seat of the trophic derangement, but the changes which have been found in the spinal cord and peripheral nerves and analogy with other known lesions like those of tabes and syringomyelia suggest a neuropathic origin similar to that of the myopathies. (6) In future cases the nervous system should be exhaustively studied.

The Rôle of the Toxins in Inflammations of the Eye.—Robert L. Randolph sums up his extensive and interesting paper as follows: (1) Bacterial toxins, so far as tested, when instilled even for many hours into the healthy conjunctival sac were found incapable of producing inflammation or causing other injury. (2) The same toxins when injected into the tissue of the conjunctiva or into the anterior chamber invariably set up local inflammation, the extent and intensity of the inflammation varying to some degree, according to the species of bacterium yielding the toxin. (3) Bacteria which had not previously been proven to produce soluble toxins were found to produce them even in young cultures, and it is suggested that injections of bacterial filtrates into the eye, particularly into the conjunctival tissue, constitute a more delicate biological test for the detection of certain toxins than the tests usually employed for this purpose. (4) The experiments recorded in this paper furnish additional examples, in a comparatively new field, of the importance of toxins in explaining the pathogenic action of bacteria, and likewise emphasize the etiological significance of injuries of the covering membrane of the eye in favoring the action of toxins and of bacteria.

The Entrance of Air into the Veins.—H. A. Hare refers to Goodridge's recent paper on this subject, and then speaks of his own and of Dr. Senn's experiments in this field. He first noticed that when in his experiments considerable quantities of air entered a vein of some of the lower animals inadvertently, no appreciable results took place even if the jugular vein received the air. He then deliberately injected air into the jugular vein of dogs and demonstrated the innocuousness of these injections. The experiments of Senn and Hare prove that small amounts of air introduced into the veins of animals practically never result fatally. Hare has seen a considerable quantity of air injected into the median basilic vein of two human beings without producing any symptoms whatever. The doses of air employed by Goodridge were so massive that their effects cannot be compared with those which are produced by those minute quantities of air which might be drawn into a vein. This writer also states that rapid injection of air is an important factor in producing bad results. It is not to be forgotten that in all probability differences in respect to resistance to air embolism exist in different animals.

Certain Characteristics of Osteitis Deformans.—Reginald H. Fitz describes the alterations in this disease, as noted by Dodd, in a series of skiagraphs, as follows: Skull much thickened, lower jaw greatly enlarged, coarse trabeculation and decalcification. Clavicle hyperostotic, the condition more marked in right than in left. Scapula, axillary border; acromion and corocoid process of right scapula hyperostotic, with foci of decalcification. A similar condition in the left scapula, but much less in degree. Humeri, hyperostotic, with coarse trabeculation and decalcification, more extensive alterations in the right than in the left. Forearm; right radius and ulna hypostatic, with decalcification; marked curvature of radius. Bones of the left forearm apparently normal. Hands; terminal phalanges of each hand show the conditions found in osteoarthritis. The right hand shows hyperostosis of the third metacarpal bone, with area of decalcification; also marked hyperostosis of the carpal end of the radius and ulna. In the left hand there are hyperostosis of the first phalanx of the thumb and a spicule of bone (?) at the inner border. The head and cortex of the fourth metacarpal bone is apparently thickened. Pelvis: there is hyperostosis and coarse trabeculation throughout the right os innominatum. Right femur: hyperostosis and coarse trabeculation throughout the shaft. The neck and head are also involved, but to a less extent. Right patella shows hyperostosis and coarse trabeculation. The tibiæ are hyperostotic, with coarse trabeculation and large areas of decalcification, more marked in the right than in the left. Cortical thickening of the right tibia and fibula. The left internal malleolus is almost wholly decalcified. The right foot shows hyperostosis and decalcification of the astragalus, os calcis, and all the metatarsal bones except the third; decalcification of the first and second metatarsal bones; trabecular structure well preserved in the fifth, but absent in the first and second bones; phalanges normal. The left foot shows hyperostosis of the astragalus, os calcis, cuboid, and internal cuneiform bones; decalcification and coarse trabeculation, especially apparent in the os calcis; hyperostosis of all the metatarsal bones except the fifth, which is apparently normal. The first phalanx of the great toe shows marked hyperostosis and decalcification. The other phalanges are normal. It would seem that hyperostosis is a condition which may affect few or many bones, early or late in life, and with inconstant symptoms; that the evidence in favor of the recognition of an independent disease—diffuse cranial hyperostosis—is insufficient, since the symptoms assigned to this affection are inconstant, and may occur in osteitis deformans.

Bulletin of the Johns Hopkins Hospital, October, 1902.

An Observation Showing that the Flagella of the Malarial Parasite Are Fertilizing Elements.—John T. Moore reports a very interesting observation that he has made. In studying the blood of an estivo-autumnal case, he saw both a granular and a non-granular body quite near together, within the field of the microscope. In the hyaline body the pigment was soon in active motion and four active flagella were quickly thrust out. The first one to free itself plunged around until it happened to come into contact with the granular body. The pigment of the latter was arranged like a wreath. After several efforts the flagellum entered this body. The ring shape of the pigment was quickly destroyed. The second flagellum that freed itself moved across the field to the granular body as if with a purpose. After many efforts to enter the body without success, it wriggled away. The other flagella freed themselves, but were lost to sight among the red blood-cells. For twenty or thirty minutes the fertilized body was watched, but nothing further was noticed aside from slight changes in its shape and the distribution of its pigment. The body which was flagellated soon became inactive and showed signs of disorganization, while the other body became slightly swollen, but showed no signs of disintegration.

The Genesis of Glioma Retinæ in Neuroglia.—Brown Pusey reviews some of the conflicting opinions held by various authorities on this subject, and gives the results of the study of a specimen stained by Mallory's neuroglia method, which was taken from a girl of four and a half years. The principal conclusion to be arrived at from the structure of this specimen is that this is a retina in which the neuroglia tissue has been developed at the expense, one may say, of the other tissues. In proof of this are the facts: (1) That the ordinary nervous-tissue elements of the retina, the rod and cone cells, the layer of bipolar cells, the ganglion cells, are either entirely absent or present in very scanty numbers. (3) The neuroglia tissue is greatly increased, as shown by Mallory's stain. Along the inner surface of the internal limiting membrane, and growing through it from the tissue outside, which in this eye represents altered retina, are cells with characteristic large granular nuclei and with varying amounts of cytoplasm, some of them containing pigment, and interlaced among these cells are long neuroglia fibers. In other words, neuroglia has invaded the cavity of the vitreous. That these cells constitute a new growth is plain also from the fact that they have invaded and destroyed the crystalline lens. Composed as it is of neuroglia, the tumor is a glioma. From the staining reaction with Mallory's neuroglia stain, there seems to be no question of the neurogliar character of the rosettes. The results from the study of this specimen certainly favor the retention for these retinal tumors of the term first suggested by Virchow, and so long accepted—glioma retinæ.

Note on a Case of Infection by Bacillus Aerogenes Capsulatus, in Which the Organism Was Demonstrated in the Circulating Blood During Life.—Rufus I. Cole presents this case. The patient was a young man who was brought to the hospital in a condition of profound shock. He had been run over by a train and both legs had been severed. The collapse was so great that it was considered inadvisable to operate, and no attempt was made to clean up the stumps. In seven hours, however, he had improved so much as to justify operation, but the patient and his friends would not consent. The night after the accident a foul odor was first noticed by the nurse when changing the compresses. The following morning both legs were found to be swollen and discolored up to the thighs. This swelling was found on palpation to be due to a subcutaneous emphysema. Coverslips made from the stumps showed a large bacillus resembling morphologically bacillus aerogenes capsulatus. Cultures were made from the local seat of infection, and cultures were also made from the blood of the patient. A rabbit was inoculated with some of the blood, soon afterward he was killed and placed in the incubator. The rest of the blood was divided among twelve tubes of litmus milk. With this, experiments were tried to test the presence of free gas in the blood. None was detected. Autopsy on the rabbit the next morning showed the characteristic lesions produced experimentally by bacillus aerogenes capsulatus. Coverslips made from the various organs and heart's blood showed the presence of an organism morphologically identical with this bacillus. After growing anaerobically for twenty-four hours the cultures made in milk from the patient's blood were found to have given rise to acidification and coagulation of the milk, the upper surface of the clot showing bubbles of gas. Coverslips made from the milk also showed the presence of these bacilli in large numbers. The organism in all these cases stained by Gram and was nonmotile. Thus the identity of the organism with that of bacillus aerogenes capsulatus was definitely determined. The cultures made from the local lesion when grown anaerobically also gave rise to a pure growth of this organism. No autopsy could be obtained. The writer adds that this case demonstrates that whatever the possibility that this organism may produce gas bubbles in the blood during life and that it may produce gaseous emboli, it is quite certain that it may exist in the blood without any, or at least with no considerable, gas production.

Annals of Surgery, November, 1902

The Identity of Proteus Infection and Hospital Gangrene.—G. R. White relates the history of a boy eight years old living near one of the Georgia swamps, and suffering from chronic malaria. He came under observation as the result of a gun-shot wound, which caused a compound comminuted fracture of the middle of the left thigh. When first seen, thirty hours after the injury, the wound was foul and discharging a dark, watery fluid. Operation was done, and gangrene developed, but after the third week the case changed for the better and healthy granulations were seen. At time of writing there was every prospect of recovery. The gangrene appeared on the day after operation, and a gaseous crepitation was felt when the flaps were pressed upon. Cover-glass smears from the sloughs showed two forms of bacilli. One was identified as the ærogenes capsulatus, and the other as the proteus vulgaris. White says that, in looking over the surgical history of the war of '61–'65 he was impressed with the great similarity of the case described with those enumerated in the History under the head of hospital gangrene. The latter was especially frequent in Sherman's army in the march to the sea, and the suggestion is made that the soil of Georgia may be peculiarly rich in pathogenic bacteria.

The "Circulus Vitiosus" Following Gastroenterostomy.—G. R. Fowler says that this term, if employed at all, should be restricted to those cases in which the stomach contents pass into the afferent or duodenal side of the loop of bowel forming the gastroenterostomy, and are subsequently returned to the stomach mixed with the duodenal secretions, including the bile and pancreatic juice. A review of the literature of the subject, as well as his own experience, leads the author to believe that the dangers most to be feared, next to collapse, during or immediately following the operation, are the occurrence of, first, the vicious circle; second, distension of the duodenum from forcible propulsion of the stomach contents directly into the afferent portion of the intestinal loop employed; and, third, reflux of the jejunal contents. While the first two may bear some relation to each other, the last named occurs independently of either of the others. If the theory that the jejunal reflux is first caused by mechanical pressure of the abdominal walls upon the efferent portion of the loop, forcing the jejunal contents into the stomach, is correct, every effort should be made to prevent the occurrence of vomiting. The author commends an operation, the steps of which are thus described. It consists, in brief, of first securing a communication between a loop of the jejunum and the stomach, then an entero-enterostomy between the afferent and efferent portions of this loop, and, finally, obliteration of the lumen of the afferent loop between the two points of anastomosis. He has selected the simplest and most rapid method of performing gastroenterostomy, and added to it a procedure which occupies but a minute or two, and yet absolutely precludes the possibility of direct intercommunication between the stomach and the afferent loop. This step in the operation, is accomplished by passing a No. 20 silver wire two or three times around the afferent loop at the point selected, and drawing upon the turns sufficiently to occlude the lumen without strangulating the wall of the intestine. The ends are twisted together, cut short, and the ends rolled into a flat coil in such a manner as to bring the cut ends in the coil, thus guarding against subsequent injury to the surrounding structures.

Archives of Pediatrics, November, 1902.

A Case of Congenital Rachitis.—Maurice Ostheimer reports the case of a child of seven months, who presented every sign of rachitis. Breast milk was stopped, as the child did not thrive upon it, and food, consisting of a certain definite percentage of fat, sugar proteids, and cod-liver oil, was given, and changed in its proportions from time to time as indicated. For three months there was marked improvement, but the child died from a severe convulsion a few days before completing her eleventh month. In spite of the absence of post-mortem confirmation, the author believes the case to have been one of those instances, rare in this country, of fetal or congenital rachitis, called achondroplasia by Parrot, and chondrodystrophia fœtalis by Kaufmann.

Pneumonia in Children.—J. P. Barber says that the writers of textbooks on the subject of pneumonia derive their experience chiefly from hospitals and asylums, and from consulting practice, and, therefore, fail to see the disease in its milder form; wherefore, they give too high a rate of mortality. The author has records of 165 cases of pneumonia in children under five years of age, seen by him in private practice. Of the seventeen cases of lobar pneumonia, one died. Of the 148 cases of bronchopneumonia, twelve died. The duration of the latter disease is shorter than the textbooks would have us believe. Out of his 148 cases 144 ended before the tenth day, and of these only three died. Climate is one of the factors which contributes largely to the low death rate and short duration of pneumonia in this city. The statistics of this disease, as of many others, should be written by the general practitioner.

Bronchitis and Bronchopneumonia in Children.—E. W. Mitchell says that in the general management of the children who "take cold" easily, the chief work is the education of the mothers in the feeding, clothing, bathing, etc. Apartments are kept too warm, sleeping rooms are not sufficiently ventilated, and too much clothing is worn. Delicate children should have a long night's sleep and a midday nap as well. They should also be gradually accustomed to a cold bath. An open-air life is the best possible means of prevention, and a useful measure for furthering the hardening process is going barefooted in summer. In the fear of draughts, windows and doors are apt to be closed in these diseases, whereas the child should come as nearly as possible to breathing outside air. Of all measures of treatment of severe cases of bronchitis and bronchopneumonia, the hot bath is the most valuable. For the control of cough, inhalations are often more efficient than medicines. In cases which become subacute or chronic, the creosote preparations are invaluable. Where dyspnœa and cyanosis are severe, oxygen is of great service, and may save life.

The Edinburgh Medical Journal, November, 1902.

The Nervous Affections of the Heart.—G. A. Gibson extols the use of exercise in the preventive treatment of nervous affections of the heart, especially of forced expiration and inspiration attended by appropriate movements of the shoulders and arms. When patients are unable to take active exercise, massage is of the highest value by the promotion of all the tissue changes. It must be carefully watched lest the blood should become surcharged with the products of metabolism and the condition of the patient rendered worse. Resistance exercises may be employed before the patient is able to take active exercise. As to the drugs to be used, alteratives, cardiac tonics, and vasodilators are the ones to be relied on. The iodides constitute the best alteratives, potassium iodide being the most efficaceous unless it is not tolerated, in which case one of the other preparations will have to be given. If there is any failure of the heart, preparations of iodine must be combined with cardiac tonics. When there is any tendency to a rise of pressure in the arterial pulse it is good practice to administer one of the vasodilators continuously in small dosage. Nitroglycerin or trinitrin is the most potent drug of its class. Its most convenient administration is in the 1-per-cent. solution, of which a dose of from one-half to two minims may be given at first. In many instances as much as ten minims may be exhibited every four hours.

Some Points in the Etiology of Tuberculosis.—Arthur Latham says that tuberculosis always results from a preexisting case of the disease, and the bacilli are conveyed by the mouth spray, by the expectoration or other discharge, and by means of food-stuffs, especially milk. It is improbable that infection often takes place from air respired through the nasal passages. The bacilli usually enter through the mouth, and may then be destroyed by the natural defensive actions of the body, or may pass into various parts of the body through direct inhalation into the lungs, by being brought in contact with the mucous membranes of the parts common to the respiratory and alimentary tracts, such as the tonsils, and then by passing through these mucous membranes, either with or without local changes, to the lymphatic vessels, and so to the cervical, tracheal, bronchial, or other glands. Or the bacilli may be carried to the stomach and intestines, pass into the lymph stream, and so cause tuberculosis of the mesenteric glands or of more distant parts. The spread of tuberculosis within the human body is by the lymphatic vessels and lymphatic lacunæ. This fact may explain why the lungs are chiefly affected in the adult, and the bronchial glands in the young child, as the age at which the change begins corresponds with the age at which a considerable alteration in the lymphatic paths in the neighborhood occurs, owing to the involution of the thymus.

Therapeutic Hints.

Obesity.—M. C. Gerhardt (*Le Bulletin Médical*) has found that eight grains of borax, three times a day, reduces the excess of fat. Smaller doses have no appreciable effect.

Typhoid Perforations.—Henry B. Potter (*The Providence Medical Journal*) says that the early diagnosis of perforation is attended with many difficulties, and requires keen judgment and ceaseless care. The symptoms of the resultant peritonitis are plain enough, but those of the perforation are extremely variable, and dependent on many collateral conditions. Undoubtedly, the most reliable signs are the sudden, continued abdominal pain, tenderness and rigidity, and leucocytosis. The diagnosis once made, no time should be lost before operation, no matter what the condition of the patient. The operation itself should be done as quickly as possible. Experience has shown that the McBurney incision is the one of choice, and that a circular suture or a single row of sutures across the perforation is sufficient. Shock does not follow operation as frequently as might be expected, seemingly no more often than after other laparotomies for peritonitis. And, finally, an early operation on a mistaken diagnosis is not attended by any material harm, which is more than can be said of a late operation with the diagnosis firmly established by the symptoms of peritonitis.

The Nature and Pathology of Myoclonus-Epilepsy.—After an introduction and historical sketch of this rare and a detailed analysis of fifty-seven cases as to etiology, interesting disease, L. Pierce Clark and T. P. Prout give symptomatology, prognosis, diagnosis, and treatment. The etiology rests largely upon a family predisposition of degeneration plus a transient and slight excitant of the character of a toxic or autotoxic agent. In the development of the disease epilepsy appears after from a few weeks to several years in one-half the cases; in rare instances the epilepsy ceases in later life. The epileptic attacks are usually grand mal in character, preceded by myoclonic spasms. For a greater or longer period of time after the fits the patient is free from his myoclonus. The myoclonus is often atypical in degree and character. There is usually much mental impairment attending the development and end of the disease. The prognosis is poor, yet life is often prolonged for years, the patient dying finally of inanition, pulmonary congestion, and premature senility. The children begotten of mycolonic epileptics usually die early of an intercurrent affection, yet they may live to develop the disease. The affection has been found in many cases indirectly as well as directly transmissible, and it is largely one of the family type of neuroses. The treatment, while largely palliative, must be undertaken with great care in the proper use of large doses of sedatives. Bromides rank in first place. The hypochlorization adjuvant principle is highly recommended. Cases not benefited by bromides are decidedly in the minority. Chloral in connection with bromides is recommended in stubborn cases. Care of the diet, general, hygiene, and a non-stimulative country existence are found to give best results. The authors present three new cases which, in addition to one previously reported by Clark, constitute the only cases of the association disease at present in English medical literature. A study of the cortex in one case under ideal conditions of methods was made, and the lesions found were in the second and third layer of cells, those of sensory and motor type. The changes in the second or sensory type are those which the authors have previously urged as the characteristic lesion of epilepsy, while those in the third or large pyramid cell are charged to the myoclonus. The lesion as demonstrated by camera lucida drawings were: A destruction of the intranuclear network and its replacement by a granular substance. As a consequence of this change in the cell body abstraction of the nucleolus occurred easily and frequently in making the sections. The exhaustive lesion of chromatolysis was shown over the entire cortex. The pathogenesis of the association disease appears to be an intoxication or autointoxication of motor and sensory cortical cells, probably brought about by a faulty chemotaxis of such because of their inherent cellular anomaly.—*American Journal of Insanity.*

Is There Any Relationship between a Duodenal Ulcer and an Injury? If So, Then What Is the Nature of the Relationship?—Walter Fowler says "Yes" to the first query, and to the second "I do not know." There is the well-known fact that a duodenal ulcer may occur as a sequel to burns. He has never yet seen this himself, but he reports four cases in which a duodenal ulcer occurred as a sequel to an injury, and in eash case the ulcer was the immediate cause of death. In the first case a penny was extracted from the gullet of a little boy by left œsophagotomy. The progress of the wound was all that could be desired, yet the boy died on the ninth day from hemorrhage from a perforated duodenal ulcer. The second case was of a man who sustained a head injury, apparently recovered, but died a fortnight later. There was a fissured fracture of the vault and also a perforated duodenal ulcer. The third case was an elderly man who had sustained an injury to his head in a street injury. There had been some parœsis of the legs which had cleared, and he was practically well, when six weeks after the injury he suddenly died. There was a small flake of lymph on the dura mater at the site of injury, and a perforated duodenal ulcer. The fourth case died of perforated duodenal ulcer, which supervened about ten days after a successful herniotomy. All the above ulcers were of very recent origin.—*Intercolonial Medical Journal of Australasia.*

Sleeping Sickness; a Suggestion.—Alexander Crombie adopts a process of reasoning by exclusion, which, he says, seems to narrow down the cause of the symptoms to disease affecting the glands which receive the lymph from the brain, as the only ones whose obstruction would presumably give rise to the phenomena of sleeping sickness. He suggests, therefore, to those engaged in the investigation of this disease, that in every fatal case of sleeping sickness, the deep cervical glands, both the upper and lower sets of both sides, should be carefully examined for signs of disease, as being the most likely seat, on *a priori* grounds, of the essential condition, probably caused by the presence of the parental form, or its aborted ova, which determines the occurrence of sleeping sickness in cases of infection by filaria perstans.—*The Journal of Tropical Medicine.*

SECTION ON MEDICINE.

Stated Meeting, Held November 18, 1902.

E. E. Smith, M.D., Chairman pro tem.

The Use of Hyoscine Hydrobromate in Morphine Habituation.—Dr. S. Ormon Goldan read this paper. He said that, before beginning the treatment of morphinism, care should be taken to be sure that the original cause was no longer effective. The method of treatment which would carry the patient for some days without suffering or without recourse to morphine was deserving of serious consideration. This suffering rarely lasted more than a week, and was generally only of from two to five days' duration. He thought these patients were better treated at home, under the supervision of a nurse and physician, than at a sanitarium, and all routine should be sedulously avoided. Hyoscine hydrobromate might be said to be a specific in morphine habituation; in other words, it was a specific means of tiding the patient over the distressing period following the restriction of the morphine. This treatment was practically a new one, and originated with Dr. M. K. Locke of Texas. The drug should be given hypodermically, beginning with 1-400 or 1-200 of a grain, to determine idiosyncrasy, and then the correct dose should be repeated hourly, or frequently enough to keep the person under the influence of the drug. After two days the dose should be repeated once in three or four hours, and after this only administered occasionally. During this entire period the patient should be kept under the constant supervision of a nurse, and as the drug produces mydriasis, the patient should be in a darkened room. Active delirium was often produced, and, therefore, the friends should be excluded as far as possible. The drying up of the secretions caused some discomfort, yet it was a useful action because of the proneness to diarrhœa on attempting to leave off the morphine. When diarrhœa did occur, it was best controlled by atropine. The speaker said that this treatment had been unfavorably criticized on theoretical grounds, but those who, like himself, had given the method a practical trial, could hardly fail to indorse it. The patient's mouth became so dry as to almost prevent swallowing, and necessitated the giving of all nourishment by the rectum.

Obstinate Subacute Rheumatism.—Dr. James J. Walsh said that many seemed to think that the salicylates were specific in rheumatism, yet those who had seen this disease treated by various coal-tar products knew that their effects were exactly like those of the salicylates. The latter really only served to lessen the pain, lower the fever, and make the patient more comfortable. It was probable that the cases proving obstinate to medication with the salicylates were due to some other cause than true rheumatism. Some of the obstinate cases were apparently the result of the invasion of pus cocci, whose virulence had been lessened by the limited supply of oxygen in the joint cavity. Not an inconsiderable number of the rebellious cases diagnosticated as rheumatism were really gout, a disease thought to be very rare in this country as compared with Europe, and yet, most carefully kept statistics from Baltimore showed gout to be one-fourth less frequent only here than in England. In many cases of alcoholic and lead toxæmia a slight injury, such as a sprain, was followed by the development of a neuritis. Anæmic patients were prone to have affections of their joints occurring almost simultaneously. These persons not infrequently have a continuance of their rheumatic symptoms for a longer time than would be expected from the use of the salicylates. The prolonged use of the latter was always harmful in such cases, because of the deleterious effect upon the blood-corpuscles. Again, most of the infectious disease may cause a passing sensitiveness in the joints. This was well illustrated in influenza, which might itself cause joint pains simulating rheumatism. If influenza preceded rheumatism a short time, the rheumatic arthritis would run a longer course than usual and prove obstinate to treatment. Patients suffering from bronchiectasis, especially if the sputum were offensive, not infrequently experienced joint pains. These were apparently the result of the toxins absorbed from the putrid material in the bronchial dilatation. Most of the cases of obstinate subacute rheumatism consist of a joint affection developing in the presence of some diathesis, such as gout, or some toxæmia, or a neurosis, or a hypersensitive condition of the vasomotor system.

Dr. T. C. Stearns said that when the salicylates were first proposed for the treatment of rheumatism, they were thought to be specific. Since that time he had watched the action of these remedies with interest. He had seen three well-marked cases of rheumatism cured, while he had observed many cases of rheumatism that had continued from year to year in spite of the administration of the salicylates. He had come to the conclusion that salicylic acid so disturbed the digestive apparatus as to prevent the taking of certain foods, which were known to be harmful in rheumatism, and in that way did some good in that disease. He did not believe that the coal-tar products had any special influence upon rheumatism. Having himself been a sufferer from rheumatism for many years, he had learned that one of the best remedies was a 2 per cent. solution of chlorine dioxide in water. It acted as an admirable antiseptic in the alimentary canal. It was also important to use sodium phosphate as an occasional laxative, and to drink water freely—say, to the extent of 3 per cent. of the body weight. This simple treatment would completely eradicate the disease. He was of the opinion that the salicylates did not have any great power to relieve the pain of any severe case of acute rheumatism. The administration of water in the manner suggested should be kept up for a long time.

Dr. A. Rose said that he was surprised at the little attention paid to the use of the warm bath in the treatment of rheumatism. Such a bath accelerated the circulation of the part, and if the latter were immersed for. days in the warm bath the good effect was quite striking. Before the days of antiseptic surgery he had learned of this treatment from Schede, and had then been deeply impressed with the value of the permanent warm bath in the treatment of severe lacerated wounds.

Pulmonary Syphilis Resembling Pulmonary Tuberculosis.—Dr. H. W. Berg was the author of this paper. (See page 926.)

Dr. Louis Faugères Bishop said that, although he had been on the lookout for pulmonary syphilis for a number of years, he had seen only one such case, and that was while in St. Luke's Hospital. This patient had entered the hospital in very bad condition, and death had occurred within a few days, the syphilis of the lung not being recognized until the autopsy. He had been impressed with what the author of the paper had said about recognizing and treating the syphilitic element in cases of pulmonary tuberculosis.

Dr. J. J. Walsh said that he had seen only one case of pulmonary syphilis, and that was one well known to American students in Vienna. The patient was a student. He had been seen by no less an authority than Professor Nothnagel, who had confirmed the previous diagnosis of pulmonary tuberculosis. The man died, and the autopsy revealed syphilis of the lung.

Dr. B. Lapowski asserted that it was a very dangerous thing to say that the lesions found in a lung of a syphilitic were due to the syphilis. Almost without exception the autopsies on cases reported to be syphilis of the lung only showed a *probability* of the disease being pulmonary syphilis. He objected to the giving of mercury by the mouth to these patients, because of the consequent interference with digestion. It was far better to use mercurial inunctions freely. Iodide of potassium was absorbed from the intestine, and not from the stomach; hence, it should be given immediately before meals, as it would then pass very quickly through the stomach and be absorbed. He was also opposed to giving iodide of potassium to a person suspected to have pulmonary syphilis; it was better to be content with mercurial inunctions, certainly until the patient was well on the road to recovery.

Dr. I. Adler said he would not accept all of the conclusions of the paper, nor did he wholly agree with those who had discussed it. He thought that the author had not given convincing proof that the case reported by him as the basis of his paper was really one of pulmonary syphilis. It was certainly most difficult to make the diagnosis even histologically of syphilis of the lungs, and to make this diagnosis by gross examination, post mortem, was usually impossible. There was, however, one form that could be diagnosticated with reasonable certainty, *i. e.* the "white pneumonia" of Virchow. Not only was the appearance distinctive, but the localization also. It was found, usually, around the hilus of the lung, in connection with bronchial glands. This variety was very rare. About twenty years ago, Dr. Adler said, he had, in conjunction with a number of physicians in various parts of this country, given antisyphilitic treatment most conscientiously to every case of pulmonary tuberculosis, and he could not say that the pulmonary affection had been influenced in the least. He was not afraid of the use of iodides in tuberculosis—in fact, he rather approved of their administration in small doses in certain forms, as for example, when there was considerable congestive bronchitis. He did not believe that syphilis was to-day a very important recognizable factor in the prognosis and treatment of pulmonary disease. He had seen but one case of congenital syphilis of the lung. This was a fibrous case, and was associated with syphilis of the other organs.

Dr. Berg closed the discussion. He said that he would grant that an examination of an isolated gumma would not afford ground for a positive diagnosis of syphilis, but pathologists were rarely willing to make a diagnosis on a section of a tumor without further examination, aided by a clinical history. But the main object of the paper was not to show that he had reported a case of undoubted syphilis of the lung, but to call attention to the fact that many more such cases probably exist than have been generally believed hitherto. Moreover, he would insist that specific endarteritis was not the exclusive property of the brain and spinal cord, and, reasoning from analogy, one should expect syphilis of the lung to be more frequent than appeared from the literature of the past. He objected seriously to giving iodide before meals, because it antagonized the action of the gastric juice, and took away the desire for food. Large doses of the iodides, given after meals, were the secret of success in the treatment of the class of cases considered in the paper. He felt sure that Dr. Adler, with his vast clinical experience, must have seen cases of the second group, *i. e.* those of slowly resolving pneumonia in persons giving a syphilitic history and exhibiting the stigmata of this disease.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held November 25, 1902.

JAMES N. WEST, M.D., IN THE CHAIR.

Myomectomy; Treatment of the Uterus by Electricity Prior to Operation.—Dr. J. H. Schmitt presented this specimen, which was removed from a virgin, forty-five years old, who had been suffering about ten years from menorrhagia with intense colicky pains at the time of menstruation, which occurred every three weeks, when she was regularly confined to her bed for several days. She hoped that with advancing age, and approach to the menopause, her betterment would set in, but her hopes were not fulfilled. Electrical treatment, extending over a period of three months, was of no avail. Finally albumin occurring in the urine, with œdema at the ankles, and her greatly unfavorable appearance, made her consent to an operation, which was performed on October 5. Except for a mere trace of albumin in the urine she was able to continue her occupation of dressmaker. The operation consisted in a total hysteromyomectomy. There was found an ovarian cyst, the size of a man's fist, and an intimate attachment of the remaining ovarian tissues of the left side to the wall of the sigmoid flexure. The diseased part of the intestines corresponded to the area of adhesions, and was thickened and without any sharp line of demarcation from the adherent ovarian remains. Upon attempting to detach the intestine a caseopurulent matter escaped. The diseased portion of the intestine was excised and the opening closed. The specimen presented showed the entire anterior wall of the uterus, down to within one inch of the internal os, and about one-half of the fundus and sides of the organ occupied by a fibromyoma, the size of a child's head, over which the posterior wall was spread. The tumor took its origin in the uterine wall and gradually developed toward the uterine cavity, becoming submucous. The violent colicky pains from which the patient suffered were caused, probably, by the attempts of the uterus to expel the tumor. The uterine cavity was distended, and so was about one foot long and eight inches across. It could easily be seen that electrical treatment, in such an instance, would be of no avail. The beneficial influence of the galvanic current was ascribed, in cases of menorrhagia produced by uterine fibroids, to the caustic effect of the positive pole. Notwithstanding such failures, the speaker believed that the electrical treatment in menorrhagia and dysmenorrhœa caused by fibroids was the best expectant method we possessed at the present time, and much preferable to the use of such drugs as ergotin, hydrastin, etc., and far superior to curettage with its dangers. The question whether enucleation or extirpation should be resorted to in cases of uterine fibroid tumors was not always easy of decision prior to operation. Often one might be compelled to desist from attempts at enucleation and resort to hysteromyomectomy and, on the other hand, one might be satisfied with an enucleation when a hysteromyomectomy had been attempted. In the case reported, enucleation of the tumor after incision of its capsule could doubtless have been performed by the vaginal route, but the unavoidable handling and traction upon the tumor might have resulted with fatal consequences. Besides the diseased adnexa would have necessitated a second operation.

Pyosalpinx Situated on the Top of the Fundus Uteri.—Dr. H. J. Boldt presented this specimen because of its unusual position and its simulation to a uterine tumor upon examination. In his opinion it was desirable to record such unusual conditions. The patient, P. M., aged twenty-seven years, began to menstruate at the age of twelve years. Menstruation was regular at intervals of four weeks, the duration of the flow being from four to five days. She was married at the age of seventeen years, and had two children, the last seven years ago. Her labors were seemingly normal. One month ago she began to have atypical uterine bleeding. She was sent to the Post Graduate Hospital because of the bleeding and pain in the left lower abdomen. When seen by him on the 17th inst. there was some distension of the abdomen and tenderness to touch over the lower abdomen. Examination under ether on the day following revealed a tumor of seemingly solid consistency on the fundus of the uterus and intimately connected with it. It seemed to have had its origin from the left cornu, and to have reached up into the abdomen to within about three inches of the umbilicus. The adnexa on the left side was not felt. The right Fallopian tube was distended. On opening the abdomen a considerable quantity of blood-tinged serum escaped. The omentum was much thickened and firmly adherent to the top of the uterus. After separating the omental and intestinal adhesions it was found that the tumor was a pyosalpinx, which had twisted itself directly upward and had become adherent to the top of the uterus. The pus had escaped from secondary small abscesses which had formed in the inflammatory adhesions and exudate. No washing of the peritoneal cavity was done. A moderately large hydrosalpinx on the right side was ruptured, the adhesions broken up, and the appendage left. The abdomen was closed. Immediately after the operation the peritonitis began to subside and the patient made a rapid convalescence. The usual site of pyosalpinx tumors was either on the floor of the pelvis or in the posterior part of the uterus. He had had one instance in which the tubal tumor was distorted to the opposite side, so that an erroneous diagnosis as to the side affected was made.

Supravaginal Amputation of Large Uterine Fibroid; Both Adnexa Attached to the Remaining Part of Uterine Structure.—Dr. H. J. Boldt presented this specimen. The operation was done because of metrorrhagia, which incapacitated the patient from following her vocation as saleswoman. She was twenty-eight years old and single. The operation itself was not difficult. It was unusual that a tumor of such dimensions, filling out the pelvis and the abdomen, should cause no disturbance other than metrorrhagia and frequent micturition. It demonstrated that it was not the large tumors which caused the greatest discomfort. It was important that we should endeavor to retain the adnexa or as much of them as possible, in all instances of hysterectomy for non-malignant disease. Furthermore, it was desirable to retain as much uterine structure as possible in all such instances, to prevent the severe symptoms of forced menopause.

Vaginal Hysterectomy for Chronic Metroendometritis of Puerperal Origin and Chronic Salpingitis.—Dr. H. J. Boldt presented this specimen, which was removed from Mrs. P. K., aged forty years, who had had her last child ten years ago; she at that time had a septic infection, which kept her in bed nearly two months. Since then she had menorrhagia, and at times metrorrhagia; she had pelvic pains, and a dragging sensation in the lower abdomen. Backache of intense character was a prominent feature. She had been under almost constant treatment since the time of her confinement; at times her condition was better, but the improvement did not continue. As a last resort vaginal hysterectomy was done. The operation was performed in June and the patient has since constantly improved, so that, according to her statements, she is now perfectly well. The uterus showed the changes of a chronic inflammatory process, and the whole history, including the appearance of the specimen, illustrated that patients who have been ill a long time with puerperal septic infection, rarely, if ever, regain perfect health; besides such uteri are likely to remain the seat of chronic inflammation.

Teratoma; Twisted Pedicle, with Impaction in Douglas's Cul-de-Sac, Simulating Pelvic Abscess of Puerperal Origin.—Dr. H. N. Vineberg presented this specimen On October 21 he was called in consultation to see a patient with supposed puerperal sepsis. She was thirty years old, had been married six years, and had had three children with normal labors, except very severe pain along the anterior part of the right thigh during each labor pain. On vaginal examination, the posterior part of the pelvic cavity was found filled with a spherical mass, which was encroaching upon the rectum. It was fluctuating, and seemed to be intimately connected with the uterus which lay in front, and appeared to be considerably enlarged. A diagnosis of pelvic abscess due to puerperal infection was made, and a vaginal incision and drainage advised. A posterior vaginal incision got no pus. Introducing two fingers into the opening he found that the cystic mass was about one inch above the incision. An opening into this with scissors was made and some puriform fluid escaped, then a mass of hair and débris, showing that he had to deal with a suppurating tumor of the ovary of a dermoid-cyst nature. Fingers within the cyst showed a solid body attached to its upper wall. The cyst was firmly fixed in the pelvis; therefore, he had the patient removed to a hospital and, two days later, performed a laparotomy. The tumor was one of the right ovary, and had its pedicle twisted twice. The tube was œdematous, almost black in color. The tumor was ablated. To the interior of the cyst was attached a solid body, about the size of a hen's egg, and bore the shape of a human fœtus. On either side at the interior part was a rudimentary leg with five rudimentary toes. In the center was a penile-like protection of almost black color from effusion of blood, due to the twisted pedicle. He had not cut into the mass to determine what internal organs were represented, but he had no doubt that it consisted of the usual aberration of organs found in such growths.

Tuberculosis of the Vaginal Portion of the Cervix and of the Endometrium, Associated with Tuberculous Disease of the Adnexa; Hysterectomy; Death.—Dr. H. N. Vineberg presented this specimen, which he had removed from a patient, thirty-seven years old, who had been married nineteen years, had had nine children and no miscarriages. Her family history was negative. Two and a half years ago she had pleurisy with effusion, for which she was tapped; this was her only illness until the present one, which began three weeks ago with pain in the lower abdomen and with fever. Menses had not occurred for two months and she had had no night sweats, no cough, no hæmoptysis, no dyspnœa, no œdema of legs. She had lost flesh and strength. On admission she was much emaciated, and had temperature in morning of 99° and 102° in the afternoon. There was retraction above and below clavicles on both sides. There was some dulness over both apices behind. No cough and no sputum. There was a murmur, probably hæmic. The uterus was found to be enlarged to the size of a gravid uterus at the sixth or seventh week. There was a mass to the left and behind the uterus the size of a hen's egg, which was firmly fixed to the uterus. The right tube was thickened to the size of the thumb. The cervix was considerably enlarged, the hypertrophy being most marked in the anterior lip, which presented large ulcerations, which were irregular in outline, moderately deep, and covered by a grayish dirty exudate, and separated from one another by narrow strips of mucous membrane of a rather bright red color. There was no marked induration of the lip, no friability of the tissues, and no tendency to bleed when touched. There was a thick, tenacious, grayish-yellow discharge from the external os. A diagnosis of tuberculous ulceration of the vaginal portion, with probable tuberculous disease of the adnexa, was made. The pathologist made a diagnosis of tuberculous disease from a portion of the ulcer, which the doctor scraped out with a sharp spoon. The operation was a very difficult one on account of the firm adhesions of the left tuboovarian mass to the pelvic floor; it was difficult to stop the oozing; the patient died six hours after leaving the table. No autopsy was admitted. On bisecting the uterus a perfect specimen of tuberculosis of the endometrium was obtained. The mucosa was double the normal thickness, and had a soft, velvety appearance, and was thrown into longitudinal folds. Fresh tubercles could be seen on the summit of folds. Tubercle bacilli were readily found in the endometrium. The right adnexa were indistinguishable as such, forming an abscess sac, the pus of which contained the tubercle bacilli in abundance. The left tube was enlarged and filled with pus, which also contained tubercle bacilli.

Uterine Polypus with Complete Inversion of the Uterus.—Dr. L. J. Ladinski presented this specimen, which had been removed from a single lady, forty-eight years old, whose menstruation had always been regular, beginning at the age of fifteen years. Four years before the doctor saw her she began to complain of pain in the lumbar region and lower abdomen. At first she suffered from menorrhagia. During the year prior to coming under his observation she complained of constant pain in the lower abdomen and profuse menorrhagia. She later had a very offensive discharge with constipation and painful urination. In June, 1902, she had a profuse uterine hemorrhage. She refused a vaginal examination for a week or two when an intact hymen was found and a profuse and offensive discharge from the vagina. A large mass was found filling the entire pelvic cavity. It was impossible for him to introduce the finger to explore the pelvic cavity to learn the origin of the tumor. The diagnosis was a tentative one of tumor of the cervix, and because of the raw eroded surface of the tumor a diagnosis of possible malignancy was made. Operation was advised and accepted. Under an anæsthetic, after dilating the hymen, he found a simple uterine polypus, and also a complete inversion of the uterus. The pedicle of the tumor sprang from the fundis uteri. The uterus was removed, and the patient made an uneventful recovery, leaving the hospital three weeks after the operation.

A Case of Appendicitis.—Dr. Ladinski reported this case. This patient had been operated upon four years ago in Bellevue Hospital for an ovarian tumor; both ovaries were removed, one four years ago, the other three years ago. The patient was a woman, twenty-six years old, who was admitted to the Polyclinic Hospital on October 3. She had had no children and no miscarriages. Her family history was negative. Her menstruation was always regular. Her patient was sent to him because of severe and irregular pain upon the right side of the abdomen, and he thought she possibly was suffering from a pyonephrosis. The urine contained granular casts, pus and gonococci. Nothing wrong could be found with the appendix. The uterus was small and both adnexa gone. On the right side there was thickening, which he thought was the old pedicle of the right broad ligament. She was kept under observation from October 3 until the early part of this month. Although she repeatedly begged for an operation, he refused to do an exploratory laparotomy. The urine cleared up, but the symptom of indefinite pain persisted, and finally he yielded to her demands for operation. Under anæsthesia he was able to examine the appendicular region. The appendix was found to lie crosswise in the pelvis, falling over the brim of the pelvis and held fast there. The diagnosis of appendicitis upon the right side was made; the cæcum was found adherent to the pedicle on the right side and held the appendix in that position. The appendix was bent over, and the omentum was adherent to the cæcum as well as to the appendix. The specimen presented showed an ulceration with fecal concretions and constrictions.

Multi-Bulbus Terminals.—Dr. P. A. Harris of Patterson said that less than one year ago he had presented to this section an intravenous injection tube of Dr. Howard A. Kelly's, which he had altered by removing the terminal at the rubber end of the tube, and substituted a conated multi-bulbus terminal in order to render it more adaptable to rubber tubing of any size. The ease with which almost any sort of tubing could be instantly and tightly connected with this multi-bulbus terminal led him to adopt it for other purposes, and he had terminals of this kind placed on all his wash-outs. Various instruments with terminals attached were presented to the section.

Vaginal Counter-Pressure Director.—Dr. H. N. Vineberg presented this instrument. He said that, although drainage following operations for disease of the pelvic organs was being restricted nowadays, still every now and then a case was met with in which such a procedure was indicated. For this class of cases he devised this instrument, which facilitated the creation of a good-sized opening through the cul-de-sac into the posterior vaginal vault. An assistant passed the instrument into the vagina and applies a grooved director, which was about two inches long and three-quarters of an inch wide, and placed at right angles to the slightly curved staff, against the posterior vault at the desired distance behind the cervix. The operator could readily cut down upon the director from above, with either a pair of scissors or a scalpel. The edges of the incision could be easily clamped with a Werthenian clamp, and all loss of blood could be thus avoided. If necessary, the edges might then be sutured with a continuous suture He had used the instrument for the past six months, and had found it very useful. The objections to the instrument which had been hithertofore used for this purpose were that it was often very difficult to thrust through a thickened and infiltrated cul-de-sac, and that the opening which was made was too small for efficient drainage and easy removal of the gauze left in the bottom of the pelvic cavity.

The Scope of Vaginal Section.—Dr. E. H Grandin opened the discussion on this, the special topic for the evening. He said that it might be laid down as an axiom that he who had specifically trained himself to work through the vagina may accomplish more and with greater facility than he who had accustomed himself to work mainly through the abdominal incision, but the conclusion that the former thus secured better symptomatic and anotomical cure would not hold. Far too frequently attempts at what might be termed surgical legerdemain resulted in incomplete and faulty work, and entailed prolonged anæsthesia with the immediate or remote effects on kidneys, heart, and lungs. Such considerations outweighed the charge brought against the man who preferred to do his work through the abdominal incision, where he might be guided by sight as well as touch. The vaginal incision commended itself for diagnosis. Thus, in those borderline cases of ectopic gestation, not at all uncommon, in which the symptomatology was so inexact that we felt impelled to defer operation, and yet where delay might be fatal, an aseptically performed vaginal section carries a minimum of risk and a maximum of certainty as regards diagnosis. If we secured free blot or clots, our line of action was clear; if we did not, the woman had in no sense been harmed. Again in pelvic pain of an obscure source, when careful examination revealed no special lesion, through vaginal section we might examine by sight the uterine appendages and determine whether or not they were causal factors of the pain. Through the same incision it was often wise to explore in order to determine the feasibility or desirability of attempting a complete operation by the suprapublic route.

A further scope of the vaginal incision was for palliative treatment. He had in mind the old-fashioned pelvic abscess, mainly of puerperal origin, in which the immediate indication was the evacuation of pus and the establishment of drainage. Here the condition of the patient was often such as to contraindicate operation from above, aside from the fact that he was a wise surgeon who dreaded flooding the abdominal cavity with puerperal (streptococcus) pus. In such an instance the posterior incision was only a step preliminary to abdominal section later, when cure was aimed at, and not palliation. The same remarks might apply to pelvic hæmatocele, except that if not suppurating, and when the condition of the patient was good, the damaged tube and the broad ligament should at the same sitting be exsected from below or above, according to feasibility. Drainage, following Nature's teaching, should be down hill, through the vaginal section. A final scope of vaginal section was for curative purposes and then we reached debatable ground. The personal equation entered largely as a factor. One man dared do much through vaginal section, where another dreaded to tread and bungle, therefore, a discussion between expert operators by different methods might be unsatisfactory. It might be granted that almost everything might be done by the vagir n of section, but too often at the expense of the patient' ination too often at the expense of an incomplete op rgery in The honest and conscientious operator did r should not, strive to see how much he could accomplish through the vaginal incision, but rather should have in mind that often the selection of the suprapubic route would enable him to work more rapidly and therefore minimize the danger of prolonged anæsthesia, and would also enable him to do more complete work and therefore be more likely to effect a cure. To sum up the matter from the standpoint of experience, he laid down the following deductions: (1) Tumors (Benign and Malignant) Unassociated with Inflammatory Pelvic Lesions.—If they could enter the pelvic brim they might be removed and should be removed through the vaginal incision. If the tumor was malignant we could perform the elaborate removal of glands which, it had been claimed, was desirable, but the experience of the writer with malignant disease of the cervix (whether operated upon from above or below), had been so uniformly unfavorable from the standpoint of recurrence that he included these cases in the category of those which might be rightly operated from below. When, on the other hand, such tumors could not enter the pelvic brim, or were surrounded by adhesions or complicated by pyosalpinx or ovarian abscesses, the vaginal incision was only feasible when the welfare of the patient did not enter as a factor. (2) Diseases of the Appendages.—Whenever readily accessible, and whenever adhesions to the neighboring structures might be separated without undue force, the diseased appendages should be by choice removed by the vaginal section. Whenever the aim was to perform plastic work on tubes or ovaries, as a rule, the same incision sufficed. Specifically speaking, pyosalpinx or ovarian abscesses, especially if right-sided, were without the sphere of vaginal section for the reason that not infrequently the vermiform appendix was also involved and must be removed, or adhesions to cæcum or sigmoid or rectum existed and might alone be surgically treated from above. This rule might occasionally not hold when the vagina was capacious. Ectopic gestation, if unruptured and not adherent, fell within the scope of the vaginal section, otherwise the suprapubic route was preferable. (3) Uterine Displacements.—In view of the fact that the symptomatology of uncomplicated uterine displacements were dependent on the amount of sagging of the organ and not on the mere version, these cases did not fall within the scope of vaginal incision. The uterus might be drawn up and held up and not merely fastened anteriorly to the vagina. Similarly, whilst elaborate vaginal incision and vaginal dissection might enable us to shorten the round ligaments by infolding or twisting, the injury to the pelvic diaphragm which was necessitated made one reluctant to sanction the method. Furthermore, of necessity, the anterior vaginal wall was foreshortened, the uterine segment became adherent and, in the event of pregnancy, dystocia might ensue. When the uterine displacement was complicated by adhesions, and, therefore, as a rule, by diseased adnexa, the vaginal incision was useless from a surgical curative standpoint, although, when the operator was specifically expert in vaginal work, he might succeed and not fear injury to the intestines, rupture of the pus-sac, or other imperfect or incomplete operation. Adhesions could be broken up through the vaginal incision and gauze could be packed, but new adhesions formed even while the old adhesions high up remain. While these views were subject to change, as were all our views at present, they were worthy of the consideration of all who placed the safety of the woman paramount to brilliancy of operation.

Dr. H. J. Boldt thought that, in naming the subject for discussion, the expression "The scope of vaginal operations" would have been better. Some years ago he had held the position that the vaginal route should always be that of choice, if it were possible to do the operation intended by that route. Many who opposed at that time now expressed the greatest enthusiasm of the vaginal route, while experience had led him to modify his views as to the scope for the applicability of vaginal operations. He now gave preference to an abdominal section in conditions in which he would formerly have advocated an operation *per vaginam*.

Suppurative Salpingitis.—In considering the individual conditions, he first took up suppurative salpingitis. Whenever the fallopian tubes were on the floor of the pelvis, and this was usually the case, and if the illness was acute, it was preferable to open the cul-de-sac, incise the pus tubes and drain them. Suppose there was pyosalpinx, either unilateral or bilateral, and it was evident that the pus sac might be readily approached *per vaginam*, but that the general peritoneal cavity was not walled off by a pelviperitonitic exudate? After opening the cul-de-sac of Douglas in the median line with a perforating dilator and then stretching the opening with a proper dilator to such an extent that the pelvic organs might be palpated, the pelvic cavity above the tubes was then walled off with sterile gauze, then the fallopian tubes were opened, and after the pus had made its exit a strip of gauze was, if possible, inserted into the opening made in the tube. The vaginal opening was also packed with gauze to check the oozing and to keep the opening as large as it had been made with the dilator. The dressings were changed every day or every other day, according to indications. The pus cavities were washed out with antiseptic solution before fresh gauze was inserted. This treatment was continued as long as pus was formed. If an exudate was present which walls off the general peritoneal cavity, the gauze packing above the tubes was unnecessary. In such cases the prognosis for the life of the patient was good. The remaining question was the relief of the patient from disease symptoms. Out of thirty-seven cases of pyosalpinx, conservatively operated upon after this manner, nine were symptomatically cured. Fifteen were improved to such a degree that they declined further surgical intervention, five were not benefited at all, and eight were lost from further observation. This was not a very good result as far as relief from disease symptoms went, but it was time enough to do a more radical operation should a patient not get sufficient relief from this. The danger of a radical operation was not increased if one first tried a simple conservative, vaginal operation. He doubted if tubes operated upon in this way ever became normal, but they might be symptomatically cured, and subsequent pregnancy was sometimes possible. In all instances of pelvic suppuration, if it was evident that pus could be reached by means of a vaginal section, that method should be preferred. So far as conservative surgery of the uterine adnexa was concerned, abdominal cœliotomy gave better results except in pyosalpinx. Fallopian tubes were sometimes so extensively diseased that their removal became necessary for the relief of symptoms which they caused, while one or both ovaries might be in such good condition that it was feasible to save them. Should it be found that diseased ovaries, not the seat of large neoplasms, were causing sufficient symptoms to give an indication for operation upon them, either anterior or posterior colpocœliotomy, as the circumstances might indicate, should be the intervention of choice. All ovarian tumors not exceeding six to eight inches in diameter and reaching to the floor of the pelvis were suitable for approach by means of vaginal cœliotomy, although it might, in some instances, be necessary, if the adhesions were too firm to be separated from below to resort subsequently to an abdominal section. In cases of tubal pregnancy, vaginal cœliotomy should be limited to those patients who had a well defined pelvic hæmatocele, and to those in whom the diagnosis had been made before rupture of the tube.

Uterine Tumors.—The presence of uterine myofibromata was occasionally an indication for vaginal operation. While submucous, and sometimes interstitial, tumors were a proper indication for resorting to this method of surgical intervention, yet if myomectomy was to be done, these neoplasms could be better treated by conservative methods if approached from above. For the vaginal operation he indicated neoplasms which were submucous, neoplasms which were on the anterior wall of the uterus, of small size, but causing irritability of the bladder, and small subperitoneal tumors which were in the cul-de-sac. For radical operations, such tumors as did not reach beyond the true pelvis, and only then if the vagina was voluminous enough to permit of the work being done without making deep incisions for the purpose of enlarging the field of work. He had given up vaginal operations for backward displacements of the uterus, preferring shortening of the round ligaments by other methods. Mobile displacements did not require opening of the peritoneal cavity at all, and patients with firmly fixed uteri could be more conservatively managed from above. If, however, a vaginal cœliotomy was contemplated because of another pathological condition, as a small myoma or an ovarian cyst, then, if displacement was present, shortening of the round ligaments should be done at the same time through the vaginal incision. The operation for ureterocystotomy *per vaginam*, and vaginal hysterectomy for cancer, depended as much upon individual circumstances as the operations on the uterine adnexa. Septic puerperal infection was not an indication for vaginal section through the cul-de-sac with subsequent drainage, unless there was an exudate into the pelvis.

Favoring the Vaginal Route.—Dr. J. Riddle Goffe said that if one could do an operation through the vagina as expeditiously as through the abdomen he saved the patient a certain amount of shock and a certain amount of danger from infection. It was generally recognized that the pelvic peritoneum was not as susceptible to infection as the abdominal or intestinal peritoneum; it was more accustomed to violent usage. Therefore, operation through the vagina was more safe than one through the abdomen to that extent. He stated that patients who had been subjected to vaginal cœliotomy were more comfortable in their convalescence, for they had no stitches to be removed, or adhesive plasters to take off, or the scarring afterward, nor do they run the dangers of a hernia following. Dr. Goffe claimed that so far as the patient was concerned, any operation that could be done as well through the vaginal as through an abdominal incision, was far better done through the vagina. The question was what operations could be done through this incision and with what thoroughness and efficiency, and with what safety? The idea of the vaginal section had changed much during the past year, and instead of opening through Douglas's cul-de-sac, the incision was extended so as to include one into the anterior vaginal wall; through such an opening not only could one feel, but also one could see, and, therefore, it was no longer a dark cavity; you were working in the light. With reference to conservative work upon the ovaries and the tubes, whether done better by the vaginal or the abdominal route, that was a matter of experience; he thought that just as nice and complete conservative work, with just as much efficiency, could be done by the vaginal as through the abdominal incision. Through a vaginal incision he could do everything that could be done through an abdominal one, and the statement that such operations could not be done *per vaginam* did not hold. He knew the older men were not looking to any change in the technique which they themselves had so perfected; but it was the younger man to whom he looked for much in this line of vaginal work. Conservative work upon the appendages he did through the vagina; even retroversions, complicated by adhesions, not only to the uterus, but to the appendages, were treated through the vaginal incision. In cases of fibroid tumors the uterus was turned down, into the vagina and removed even easier than through abdominal section. He believed that uterine fibroids below the brim of the pelvis could be treated with as prompt satisfaction by myomectomy through the vagina as through the abdominal incision. In conclusion he stated that there were more operations being done through the vagina than through the abdomen as the younger men are growing.

The Limitations of the Vaginal Route.—Dr. A. Palmer Dudley, because he looked upon the question under discussion from purely a mechanical standpoint, said he must disagree with some of the gentlemen. He did not want to be limited to any one method of operating; in fact, the more methods he had of doing work within the female pelvis the better. In studying the scope of vaginal work, and its limitations, one must individualize, and that one could do. There were master workers in the vagina, and master workers in the abdomen, and they disagreed because one could work better from above and the other from below. The woman's life and her after-condition depended upon the skill of the man she chose, whether he did his work through the vagina or through the abdomen. He could only praise the man who could work through the vagina with the same skill as one could do the same work through the abdomen. What were its limitations? He believed it was only the work that could be done through the vagina that had its limitations, and he believed that only such work in the pelvis or abdomen which could not be reached through the abdomen should be done *per vaginam*. The limitations of the vaginal work in the hands of experts, such as Dr. Goffe had proven himself to be, were anything that they could draw through the pelvis with safety to the woman. If they could do that through the vagina they were justified in so doing; but, if they endangered the lives of their patients by such individual idiosyncrasies, they were then taking such chances which the general profession would condemn.

Dr. H. N. Vineberg, in continuing the discussion said that by the term vaginal section, as he understood it, vaginal hysterectomy was excluded, as was also the operation which was performed for the correction of uterine displacements. Vaginal section found its scope in the following conditions: (1) Pelvic Abscess—In cases of simple pelvic abscess, when the collection of pus occurred in the cellular tissue of the pelvis. When the collection existed in Douglas's cul-de-sac the section was both easy and simple. When the collection had taken place at either side of the uterus, in the base of the broad ligament, the vaginal incision was attended with considerable risk, notably from hemorrhage. When the collection was in front of the cervix, the position of the bladder had to be taken into consideration. (2) Pyosalpinx and Ovarian Abscess.—In his opinion vaginal section was indicated in these lesions only under certain conditions: (*a*) When the abscess sac was easily reached through a vaginal incision and could be removed entire, *i. e.* when it was situated in Douglas's cul-de-sac and was fairly movable. (*b*) When the sac was not large and could not be removed readily through an anterior vaginal incision. (*c*) In pyosalpinx and ovarian abscess, during the acute stage, vaginal section was indicated if the collection of pus was accessible through a posterior incision through the vagina, simply to tide the patient over the dangerous period. In some cases, when the pus sac was unilocular and favorably situated, the vaginal section may prove to be not only palliative, but a curative measure. There was a class of cases of acute and subacute pyosalpinges, which it was customary to treat palliatively for weeks, in the hope that the pus might become sterile. These cases could be safely attacked through a vaginal and abdominal section combined. By pursuing such a plan the patient was saved a long illness in bed and sometimes from an extension of the lesion through repeated attacks of inflammation during the waiting period. (3) Conservative Surgery in

Diseased Adnexa.—Vaginal section found a suitable field in a certain class of diseased appendages admitting of conservative surgery. The cases required to be selected. But after some experience in selection and the requirement of some skill in operating through the vaginal route, a mistake was seldom made in setting the indications. He excluded all cases in which there were extensive and firm adhesions and when there were evidences of marked infiltration of the broad ligament. (4) Ovarian Cysts.—One met with a number of ovarian cysts of moderate size which could be readily removed through a vaginal incision. Before deciding upon this route one should be reasonably certain that he was dealing with a simple cyst and not with an abscess of the ovary. (5) Myomectomy.—Small fibroid growths in the anterior wall of the body or fundus of the uterus constitute a suitable field for the vaginal route. Growths in the posterior wall, if they were situated high up had better, in his opinion, be removed from above. (6) Ectopic Pregnancy.—In this condition vaginal section was indicated under the following conditions: (*a*) in obscure cases, to aid in forming a diagnosis; (*b*) in cases of ectopic pregnancy, when evidently there are no further hemorrhages and when the already effused blood has formed a hæmatocele in the cul-de-sac or at the base of one of the broad ligaments. It was a good plan to pass the fingers into the cavity of the hæmatocele for the purposes of exploration. If a mass be found projecting from its upper wall, it was usually the ectopic sac containing an organized blood clot. In such a contingency he deemed it was safer to open the abdomen from above and remove the mass. When this had not been done he had known serious hemorrhages to recur after the patient had been returned to bed.

Dr. Brooks H. Wells said the first vaginal sections for disease of the appendages were made by the late Wm. F. Byford of Chicago, in the late '80's. But one was seldom a profit in his own country, and the operation was overlooked and forgotten. Later it came back with the glamour of a foreign fame and many surgeons became so enthusiastic as to say they would never again cut through the abdominal wall for conditions that could be reached through the vagina. When they came to their senses again they found that while all the conditions under discussion *could* be treated by vaginal section yet the ultimate results were not in all cases as satisfactory as those obtained by the abdominal route. Granted that the mortality was essentially the same by either route, what were the advantages claimed for the vaginal section? (1) The avoidance of the visible abdominal scar and the liability to neutral hernia. The chance of hernia was remote with modern methods of wound closure. The discomforts of the visible scar were often more than counterbalanced by the dyspareunia from the scar hidden in the cul-de-sac. (2) The smoother, quicker, and less painful convalescence. His own experience, as well as that derived from the observation of many cases of other operators, was just the reverse, except in the instances in which the vaginal operator was able to leave a closed wound, as in the method usually employed by Goffe, the clamp operation was done, or any method employed, which required the repeated packing of the vagina with gauze, the frequent dressings required were often extremely painful, and there was usually a foul discharge. In abdominal work these sources of discomfort were avoided. (3) That, as there was less disturbance of the abdominal contents in operations by the vaginal route, fewer adhesions resulted.

In simple conditions, these needed little disturbance by either route. In difficult cases it should be evident to every practical surgeon that one could separate complicated attachments more safely and accurately through the abdominal incision, and that one could better cover over and repair injuries to the peritoneal surface by this route. The more completely peritoneal surfaces could be restored, the less the probability of the formation of new adhesions. The fewer the adhesions the better the ultimate result. These considerations sharply defined the scope of vaginal work. When we wished primarily to drain the pelvic cavity, as in certain cases of puerperal sepsis, or large collections of virulent pus, vaginal incision was proper. In other conditions we should, in the great majority of cases, enter the abdomen from above.

Book Reviews.

A Text-Book of the Science and Art of Obstetrics. By Henry J. Garrigues, A.M., M.D., Consulting Surgeon to the New York Maternity Hospital; Gynecologist to St. Mark's Hospital; Professor Emeritus of Obstetrics in the Post-Graduate School; Honorary Fellow of the American Gynecological Society and of the Obstetrical Society of Edinburgh. Philadelphia and London: J. B. Lippincott Company, 1902.

For many years the science and art of obstetrics seemed to be at a standstill, and the books on this subject which appeared from time to time represented little more than old knowledge in a new dress—indeed, as regards the illustrations, even this was not true, for one book after another copied the cuts of the old masters, errors, inaccuracies, and all. The last few years have seen a great change in this respect, and very naturally, for the present teaching of obstetrics is as different from that of the past as daylight is from darkness. The improvements in the bookmaker's art, especially in the reproduction of illustrations, have also done much for the student of obstetrics. In the present work he is given a clear, logical, and systematic presentation of the subject, for the author, unlike many others, never falters in his determination to teach, and to avoid confusing his pupils by lengthy discussions and unnecessary details. On the other hand, everything that is really of importance is described with great minuteness.

There are two grand divisions of the book; the first, dealing with what the author calls "the foundation," and with normal pregnancy, labor, and the puerperium; the second, treating of abnormal pregnancy and labor, obstetric operations, the abnormal puerperium, and the diseases of the new-born child. The many illustrations have been selected with a view to elucidating the text rather than making the book attractive.

Everywhere may be seen the touch of the experienced teacher and practical obstetrician. The common-sense advice with regard to the question of adopting antiseptic or aseptic methods in the average private practice is a case in point, and the lucid and detailed instruction for the acquisition of that most useful art, the palpation of the fœtus through the abdomen of the mother, is deserving of special commendation. A distinguishing feature, which will be appreciated by the novice, is the fulness of the information on the subject of the care of the breasts, and on the diseases of new-born children. Altogether this is a textbook in the best sense of the word, yet it may be profitably consulted by the practitioner. The author's style is clear, concise, and characterized by a refreshing candor. Dryness is avoided by interrupting here and there the flow of scientific precept by touches of humor, and even of pathos, not a few of which, like the following, disclose both the teacher and the man: "Upon the whole," he says, "most women approach their confinement with a serious turn of mind, which, in some, amounts to apprehension and dread, sometimes mixed with despair. The humblest woman who is going to give birth to a child should, therefore, inspire her accoucheur with genuine sympathy. His knowledge and skill, however great they may be, do not suffice; he must feel with his patient, pity her sufferings, think of her dangers, forgive her sins, comfort and encourage her, and not forget that she is going to give birth to a human being, perhaps one of Nature's favorites, maybe one who will become a benefactor of mankind."

Practical Diagnosis: The Use of Symptoms and Physical Signs in the Diagnosis of Disease. Fifth Edition, Revised and Enlarged. By Hobart Amory Hare, M.D., B.Sc., Professor of Therapeutics in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital; One-Time Clinical Professor of Diseases of Children in the University of Pennsylvania, etc. Philadelphia and New York: Lea Brothers & Co., 1902.

The appearance of this new edition of Hare's Diagnosis will be warmly welcomed by the many who have been helped by the teachings of earlier editions to a correct appreciation of the significance of various obscure symptoms. The plan of the work is eminently rational and practical. Instead of beginning with the disease and describing its symptoms, as is done perforce in textbooks on the practice of medicine, the author begins with symptoms, and discusses the diseases to which they point. In this way the book serves as a guide-post in the labyrinthine paths of diagnosis, which is the only *raison d'être* of works of its class. This new edition has been considerably amplified; new matter relating to physical signs and clinical tests has been added; former teachings have been revised to keep pace with the progress of medical science; and many illustrations and colored plates have been inserted. The work is one well adapted to the needs of the practitioner, especially the young one who has yet to acquire fluency in reading the obscure hieroglyphs of disease.

Cliniques Médicales Iconographiques. Par M. P. Haushalter, G. Etienne, L. Spillmann, Agrégés de la Faculté de Médecine de Nancy, et Ch. Thiry, Ancien Interne des Hôpitaux de Nancy. Paris: C. Naud, 1901.

This great atlas of medicine, which is published in eight parts, contains sixty-two quarto plates, composed of 398 phototypes, illustrating 284 separate cases. Accompanying each plate is a brief history of the case depicted, care being taken to point out to the more obscure features in each instance, which might otherwise escape the untrained eye of the observer. The photographs are those of actual patients treated in the authors' clinics at Nancy. Many of them are of the same disease, illustrating various forms, stages, and individual peculiarities of progressive amyotrophy, infantile paralysis, and hemiplegia, Graves' disease, myxœdema, gangrene, arthritis deformans, etc. Thus the student is not misled by the contemplation of types only, but becomes acquainted with the physiognomy of disease in all its varieties. In addition to the many nervous affections which lend themselves so readily to pictorial representation, there are illustrations of the cutaneous manifestations of general diseases, of the various trophoneuroses, dermatoses, and syphilitic changes. The work cannot be commended too highly for the excellence and fidelity of the plates, and the instructive histories of the subjects of the illustrations. With it, in conjunction with a good textbook of medicine, one may pass many profitable hours in clinical study.

A Manual of Medical Treatment, or Clinical Therapeutics. By I. Burney Yeo, M.D., F.R.C.P., Emeritus Professor of Medicine in King's College, London; Consulting Physician to King's College Hospital; Hon. Fellow of King's College; Formerly Professor of the Principles and Practice of Medicine and of Clinical Therapeutics in King's College; Examiner in Medicine at the Royal College of Physicians, etc. Tenth Edition. Chicago: W. T. Keener & Co., 1902.

This treatise differs from many of the best known works on treatment in that it is not a mere therapeutic index giving a list of medicinal and other measures for combating disease. Treatment is much more largely symptomatic and causal than specific, and consequently a knowledge of etiology and symptomatology is essential to a rational and successful therapy. This fact has been recognized by Dr. Yeo, who devotes much space to the causation, pathology, and symptoms of each disease before entering upon its therapeutic management. A feature of the book which will appeal to many who are rather weak in prescription writing, and love ready-made formulæ, is an appendix to each chapter containing a number of the "favorite prescriptions" of various well-known clinical teachers and therapeutists, in addition to those given by the author himself. There are some recommendations in the book with which the reviewer cannot agree, and several omissions which he regrets—in the chapter on pneumonia, for example—but he rejoices to find here a condemnation of the routine cold-bath treatment of typhoid fever. The reprobation of this practice by an authority such as Burney Yeo should make the heedless stop and think. This edition does not differ greatly from the one preceding—indeed, where a new edition comes out every year, the changes cannot be many—but all necessary additions have been made to keep the work thoroughly up to date.

The Public and the Doctor. By a Regular Physician. Published by Dr. B. E. Hadra, Dallas, Tex.

This little book of 150 pages is intended to instruct the public regarding its relations to the medical profession. It will serve to explain many points to the layman which will enable him to select his doctor with better judgment than is always shown, for it points out the dangers and fallacies of quackery, Christian Science, etc., in a way that would be convincing to anyone endowed with the power of judgment. The author lays stress upon the long time required for study and for work in the domain of medicine and the absurdity of the claims of exceptional knowledge, with which the advertising healer crowds the newspapers. Good, wholesome advice abounds, and the reader should make a better patient after the perusal of the booklet. To those physicians who have not the time or disposition to explain these points to their clients the work can well act as a substitute teacher

Applied Surgical Anatomy Regionally Presented for the Use of Students and Practitioners of Medicine. By Geo Woolsey, A.B., M D Professor of Anatomy and Clinical Surgery in Cornell University, Surgeon to Bellevue Hospital, etc With 125 illustrations, mostly colored New York and Philadelphia Lea Brothers & Co., 1902

For the purposes of instruction, the relations between anatomy and surgery cannot be too early brought out in the college courses and emphasized. The volume before us is one of the most recent attempts to present surgical anatomical information in a concise and comprehensive manner, and the author may be congratulated upon a successful effort. As is to be expected, the various chapters of the book are devoted to the different regions of the body, the anatomical points of which are described with special reference to their surgical importance, though strictly anatomical detail is by no means neglected. The author has drawn largely from various sources for his illustrations, which are numerous and serve their purpose, but are not particularly noteworthy. The student for whom this book is specially written will no doubt find it useful, and it will also fill a place on the reference shelf of the graduate, though no well-established predecessor is likely to be thus displaced.

The Physician's Protective Accountant. Chicago: The Clinic Publishing Co., 1901.

This is a combined visiting list and pocket ledger of monthly balances with index of accounts, which the publishers claim is the only strictly legal pocket visiting list and financial record in existence. The visiting list comes in twelve sections, each of which can, in turn, be inserted in a flap in the inside cover of the ledger. Each section contains space for the records of 128 patients, two on a page, a whole line being available for entry of the kind of service rendered each day in the month, and the amount charged therefor. At the bottom of each page is space for the total charges with credits, if any. If the account is paid within the month, there is nothing further to do than to enter the collection in the cash account for the month at the back of the ledger If it is not paid, it is transferred to the ledger, a very simple matter, since both visiting list and ledger are contained within the same covers. The advantage of a visiting list in which the nature of the service rendered is written out in full, and not expressed by signs, is that in case of death of either physician or patient a legal record exists, the courts having held that accounts requiring explanation will not stand The book is of convenient size for the pocket, of moderate price, ingenious in its arrangement, and yet so simple that no one would be likely to make errors in his accounts while using it.

The American Text-Book of Obstetrics. By various authors. Richard C. Norris, M.D., Editor; Robert L. Dickinson, M.D., Art Editor. Second Edition. Two volumes of 550 pages each; nearly 900 illustrations. Philadelphia and London: W. B. Saunders & Co., 1902.

Since this now well-known work first made its appearance in 1895 there have been many advances in obstetrics, and the present edition has afforded an opportunity for revision and extensive additions. It now appears in two volumes. The high standard of artistic and typographical excellence which marked the first edition has been fully maintained in the present one. The first volume deals with the generative organs, pregnancy and labor; the second, with the puerperium, the new-born infant and obstetric surgery. The great wealth of illustration impresses one at every turn, but special mention should be made of the plates accompanying the article, by Dr. George A. Piersol of Philadelphia, on the development of the embryo, and those showing the mammary changes of pregnancy, described by Dr Chauncey D. Palmer of Cincinnati, in his article on the symptoms and signs of pregnancy. The all-important, but rather difficult, subject of the mechanism of labor is admirably presented by Dr. Edward Reynolds of Boston, and he who will implicitly follow the judicious instructions of Dr Charles Jewett of Brooklyn, on the conduct of normal labor, will never have occasion to regret it The subject of obstetric surgery is subdivided into instrumental operations and manual operations. The former is treated of by Dr J. Chalmers Cameron of Montreal, and the latter by Dr. Robert L. Dickinson of Brooklyn Here, as elsewhere throughout the work, the numerous high-class illustrations help to a proper understanding of the subject.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 6, 1902:

	Cases.	Deaths.
Measles	160	6
Diphtheria and croup	397	49
Scarlet fever	191	12
Smallpox	1	..
Varicella	86	..
Tuberculosis	259	164
Typhoid fever	90	16
Cerebro-spinal meningitis	..	..

Purulent Phlebitis of the Sigmoid Sinus.—A. Knapp reports the case of a patient with unquestioned pyæmia of aural origin, having two to three chills a day, at operation presented an enormously distended sinus with a thin but healthy anterior wall; the sinus contained fluid blood. The sigmoid sulcus was normal. The bone posterior and external to the horizontal semicircular canal seemed unhealthy, and the neighboring dura was covered with apparently healthy granulations. The pyæmic condition, though improved at first, continued; the swelling in the right suboccipital triangle became circumscribed. At the second operation the floor of the occipital bone was explored to no purpose, and as the bone near the labyrinth seemed unhealthy, this was further resected. No new lesion was found. The lateral sinus still contained fluid blood. The jugular vein was ligated. The patient's condition grew steadily worse; meningitis became more marked, and led to the patient's death. At autopsy, meningitis was found, and an unusual condition of the sigmoid sinus. The descending portion was enormously distended, the anterior wall was very thin, but healthy. The posterior wall was thickened, measuring 6 mm.; all of the coats of the venous wall were infiltrated, the central part was red, and the part projecting into the lumen was gray and rough, apparently necrotic. Microscopic examination of the sinus wall revealed the presence of granulation tissue, showing that the process was of some standing and tissue repair had been attempted. This infiltration extended down through the bulb to the beginning of the jugular vein, thus producing the deep suboccipital induration. The cerebellar surface of the dura appeared perfectly healthy. The sinus contained a recent blood-clot. The infection presumably extended from the antral wall posterior to the horizontal semicircular canal to the dura, causing pachymeningitis, then involving the posterior wall of the sinus, the anterior remaining healthy.—*Archives of Otology.*

Two Cases of Anæsthetic Leprosy.—C. N. Valin reports two cases of this disease which occurred in his practice, and which, he considers, prove the contagiousness and the curability of leprosy. The first patient was a Syrian boy, thirteen years old, who arrived in Montreal in December, 1899. He had no cutaneous trouble on arriving, but did have fever, headache, and other symptoms, and a few months later the characteristic symptoms of his affliction declared themselves. In the lack of any specific treatment, the oil of chaulmoogra, which has been given in leprosy with good effects, was administered, and in two months there was a notable improvement in the patient's condition. The fever and lassitude disappeared, the appetite improved, the general condition became better, the spots on the skin gradually disappeared, œdemas and infiltrations were absorbed, and sensibility was restored in the anæsthetic areas. The cure has been maintained for a year and a half. The boy's father, who has been in Canada nine years, never showed the slightest symptom of leprosy until about two years after his son's arrival. He is now suffering from the disease, which, in the absence of all other possible sources of infection, he must have contracted from the boy. The author treats of the subject of leprosy at length, and suggests measures of sanitary prophylaxis.—*L'Union Médicale du Canada.*

The Early Diagnosis of the Attacks and Relapses of Acute Articular Rheumatism.—P. Achalme calls attention to a new symptom which consists in a temporary but decided cardiac arhythmia preceding the articular attacks. It is a true arhythmia and not a plurigeminal pulse; the number of the pulsations diminish and oscillate between fifty and sixty a minute, which is the opposite of the condition found in the arhythmia,of neuropathies toxic asystolic arhythmia, etc. At the same time the force of the cardiac impulse is increased. The patient complains of fatigue, and of apathy, but has no symptoms which he refers to the heart. This symptom begins abruptly and at once reaches its maximum of intensity, diminishes later, and lasts altogether from forty-eight to seventy-two hours. It has usually disappeared when the fever and the articular troubles make their appearance. The author inclines to the belief that there is a lesion of the myocardium due to the localization of the microbes of the disease, basing this view upon the results of experimentation on animals.—*Archives Générales de Médecine.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended December 6, 1902:

THE SYSTEMIC OR CONSTITUTIONAL CHARACTER OF GONORRHŒA; ILLUSTRATED BY FIVE CASES OF IRIDOCHOROIDITIS.

By CHARLES STEDMAN BULL, M.D.,
NEW YORK.

During recent years evidence has been gradually accumulating of the constitutional character of the gonorrhœal infection. Many cases of undoubted systemic infection of various kinds, and in different parts of the body, have been reported, all tending to cast great doubt on the purely local character of the disease. For twenty years or more a direct connection has been recognized between gonorrhœa and endocarditis, and, since the investigations of Bumm, in 1887, of the gonococcus of Neisser, we have come to admit the part played by the gonococcus in the production of general constitutional complications. Whether the general system is invaded by the gonococci themselves or by the toxins developed from them, is, however, still a moot point. The theory that the systemic infection is due to the absorption of a toxin derived from the gonococcus and liberated from the bacterium in the course of its destruction is very difficult of proof.

The gonococci penetrate the general system by way of both blood vessels and lymphatics. They have been found in the blood of patients suffering from ulcerative gonorrhœal endocarditis (Thayer and Lazear), and of patients attacked by gonorrhœal rheumatism. It is admitted that gonorrhœal urethritis may be the starting-point of a fatal septicæmia, and that endocarditis and arthritis are often complications of this infectious disease. It is also recognized that endocarditis may be caused by the gonococcus alone; for it has been obtained in pure culture from the blood, from the heart structure and endocardium, from the joints, and from the aortic valve vegetations. (See Thayer, Dauber, Borst, Lazear, Rendu, Haller, and Lenhartz.) (See also Lartigan, *American Journal of the Medical Sciences*, January, 1901.)

In those instances of sudden loss of sight in patients affected with septic endocarditis, which have been attributed to a clot or plug coming directly from the heart or aorta, a recent explanation has appeared that the loss of sight is occasioned by obliteration of the retinal vessels themselves, whence comes partial or total thrombosis, affecting the optic nerve and retina. This view seems to be supported by the researches of Koenig, Martin, Leyden, Wertheim, and Potain. If the aorta and heart can be attacked by the gonococcus, it is natural to conclude that the retinal thromboses may be due to a localized gonococcic inflammation of a similar nature.

As regards gonorrhœal rheumatism, the facts are not so corroborative of the constitutional character of the disease. It is not so certain that the arthritis accompanying gonorrhœal urethritis is a localized product of a general infection. Gonorrhœal rheumatism is met with only in about 2 per cent. of gonorrhœal cases, and, though the gonococcus has been found in inflamed joints, the cases reported are too few on which to base any conclusions.

As regards the inflammation of the uveal tract of the eye occurring in the course of a gonorrhœa, we have more positive evidence of its dependence on systemic infection. It develops much more rapidly than the ordinary rheumatic iritis and choroiditis, and the plastic character of the inflammation is less pronounced, it being rather of the serous variety. It is not an uncommon complication in patients affected with gonorrhœa, and here it must be regarded as directly connected with the urethritis. The inflammation of the uveal tract never seems to follow the urethritis immediately, but is invariably preceded by an arthritis, usually of the knee-joint. The iritis or choroiditis is very distinct from the usual type of rheumatic inflammation. It is very sudden in its onset, very rapid in its development, the pain is exceedingly severe, and the loss of vision is very rapid and complete. But the inflammatory process, though obstinate and subject to frequent relapses, eventually rapidly subsides, and, usually, leaves little or no trace behind it. There is almost never any gelatinous or fibrinous exudation in the anterior chamber, and the main cause of the rapid and marked deterioration of vision seems to be due to a general serous infiltration of the iris and choroid, and a diffuse serous exudation into the aqueous and vitreous humors, more marked in the latter. Posterior synechiæ do form, but they are readily broken and, as a rule, leave no trace behind on the anterior capsule of the lens. Such an iritis, or iridochoroiditis, is liable to relapse, even when no adhesions are present, whenever the patient contracts another attack of gonorrhœa. A neglected gonorrhœal iritis, in which multiple adhesions have been formed, may, of course, readily relapse, and, in consequence of these relapses, the symptoms of the disease gradually lose their peculiar character. The disappearance of the iritis under appropriate treatment, without leaving posterior synechiæ, proves the absence of the plastic character. Its prompt disappearance distinguishes it, also, from the usual form of serous iritis.

Some authors, among them De Wecker, think that there is a class of patients who never suffer from arthritis or iritis unless previously attacked by a gonorrhœa, and when the inflammation of the joints and iris is cured, it does not recur unless a fresh attack of gonorrhœa is contracted. They believe that the tendency of certain diseases, in which there is more or less of an infectious character, to localize simultaneously in the eye and in the knee must rest on some identity of anatomical disposition furnished by the structure and division of various vessels. Leber believes that, in the course of a real, specific urethritis, a lesion of the mucous membrane occurs, and that the microscopic germs developed by the urethritis thus find their way into the general circulation, and, eventually, cause the inflammation in the eye and joints. However that may be, clinically speaking, the symptoms of a gonorrhœal iridochoroiditis are usually very much more severe than the ordinary rheumatic form of the disease, and always suggest a very unfavorable prognosis, which our experience with these cases teaches us is almost never confirmed by the results of treatment. No matter how severe the symptoms may be, if the case be properly and persistently treated, the inflammation eventually rapidly subsides, without leaving any marked impairment of vision.

Case I.—A gentleman, aged thirty-three years, came under my care on November 12, 1900, and the family physician gave the following history: A number of years before he had contracted a very severe gonorrhœal urethritis, which lasted a long time, frequently relapsed, and had never been cured. He had suffered from gonorrhœal arthritis of the knees and ankles at various times. Early in November, 1900, while ill with inflammation of the knee and ankle-joints, he developed a purulent conjunctivitis of both eyes. I saw him on November 12, and found the lids of both eyes swollen and dusky, considerable chemosis of the conjunctiva, and a profuse, purulent discharge. Smears were taken from the conjunctiva and examined, but no gonococci could be found. There was a gleety discharge from the urethra, which was found to contain broken-down gonococci. I gave a favorable prognosis on account of the absence of gonococci from the secretion. The attack lasted nearly three weeks, but a cure then resulted with unimpaired corneæ. On December 24 the right eye again became very inflamed and painful, but with no swelling of the lids and no discharge. I saw him on the 29th of December, and found well-marked iridochoroiditis, with posterior synechiæ and exudation into the vitreous humor. With the onset of the inflammation in the eye, the arthritis of knees and ankles began to grow better. Continuous hot fomentations were ordered to the eye; atropine and cocaine, locally, every two hours, and sodium salicylate, five grains every hour, were prescribed. Vision rapidly failed, and in less than three days the eye had no perception of light. In one week the symptoms began rapidly to subside, and in about three weeks vision was restored nearly to the normal. This patient's case was one of unusual interest, because of the obstinacy of the eye-disease and the frequent relapses. Less than one month after the first attack in the right eye, the left eye became inflamed in the same way and with the same rapidity. Between December 24, 1900, and April 20, 1901, he had four relapses in the right eye and three in the left eye. With each attack of iridochoroiditis, the symptoms of pain and stiffness in the joints became less marked. From each attack the eyes recovered with useful vision, and, when I last examined him, on June 19, 1901, the vision was normal in each eye, the accommodation had been restored, all infiltration had disappeared from the vitreous humor, and the fundus was healthy. This patient showed the most profound degree of gonorrhœal saturation that I have ever seen, for, in addition to the iridochoroiditis and the multiple arthritis, there was a well-marked endocarditis, which lasted for a long time and interfered greatly with the general constitutional treatment.

Case II.—A gentleman, aged 28 years, came under my care early in October, 1891, and gave the following history: He had worn glasses for near work, and an examination showed that he was highly astigmatic and had very weak internal recti muscles. The glasses were cylindro-prisms, and were correct. He had had two attacks of gonorrhœa several years ago. The last, and most severe, attack was contracted in the preceding August, and still persisted. Early in September he had an acute attack of arthritis in the right knee and left shoulder-joints, which lasted nearly four weeks. The inflammation then subsided in the shoulder, but the knee was still inflamed when I first saw him. Two days before he came under my care there was an acute exacerbation in the knee-joint, and the right wrist also became inflamed, and that same evening the right eye became inflamed with severe pain, photophobia, and lachrymation, and rather rapid loss of vision. Two days later I saw him, and found a severe case of iridochoroiditis, with marked ciliary injection, exudation into the anterior chamber and vitreous, posterior synechiæ, and increased tension, and vision was reduced to $^{20}/_{200}$. No view of the fundus could be obtained, and there was very severe pain. The left eye was intact, and remained so throughout the duration of the attack. Leeches were applied to the right temple, a solution of atropine (4 grains to the ounce) was instilled into the right eye four times a day, and hot fomentations were ordered for half an hour every two hours. Five grains of sodium salicylate were ordered to be taken every hour, until the stomach rebelled. Smears were taken from the urethral discharge, and an examination showed them to be loaded with gonococci. The patient had never had any rheumatic trouble, and no trace of any arthritic inflammation existed in the family. Three days later the administration of the sodium salicylate was stopped, on account of gastric disturbance. All pain in the eye had ceased at the end of the second day, and the media began to clear. One week later there was an exacerbation of the inflammation in the right knee-joint, and, coincident with it, a relapse of the iridochoroiditis. The sodium salicylate was again administered, the local applications being continued. Ten days later he had another relapse, and, under my advice, active local treatment of the urethritis was instituted with protargol injections. Within three days a marked improvement began in the eye and inflamed joints, and the vision, which had sunk to perception of light, so improved that, in three weeks from the date of the last attack, it reached the normal standard of $^{20}/_{20}$. The arthritis of the wrist-joint disappeared, and all pain and swelling subsided in the knee-joint, though it remained quite stiff. From the time of the last attack, potassium iodide, in ten-grain doses, was administered daily until he had passed out from under my observation.

Case III.—A gentleman, aged thirty years, contracted gonorrhœa in the latter part of November, 1901. He had two previous attacks, the first one seven years before, and the second one two years before. In all of them he had been treated by his family physician. The first attack was entirely cured, but the second one was followed by a chronic gleet. On December 10 a severe orchitis developed, and two days later acute arthritis of the right knee and ankle appeared, accompanied by severe pain and great swelling. This patient had never suffered from rheumatism, but there had been several cases of acute arthritis in his family. He was treated by hot saline baths and potassium iodide and salicylic acid internally, but with little apparent effect. On December 20 the right eye became inflamed, and, after a painful night, I was sent for. I found a moderate swelling of the lids, some chemosis of the conjunctiva, great conjunctival and ciliary injection, and all the signs of acute iridochoroiditis. The vitreous was so cloudy that no view of the fundus could be obtained, and the vision was reduced to counting fingers; all these symptoms developed within twenty-four hours of the onset of the disease. Leeches were at once applied to the temple, hot fomentations were applied to the eye for half an hour every two hours, a four-grain solution of atropine was instilled every two hours, and the patient was directed to take five grains of sodium salicylate every hour as long as the stomach would bear it. The patient's stomach would not tolerate the drug, and, after the first day, it was changed to the salicylate of cinchonidia, under which he did very well. Three days later the left eye became inflamed, the iridochoroiditis developing more slowly than in the right eye. The same treatment was followed, and there was a slow but steady improvement till the tenth day, when a relapse occurred in both eyes. As the eyes grew worse, the arthritis in knee and ankle grew better, and when improvement began in the eyes, the inflammatory symptoms in the joints became more pronounced. This patient had three relapses in the right eye and three in the left eye, and the treatment was prolonged for nearly three months before he could be discharged from treatment. His vision was then $^{20}/_{20}$, or normal, in both eyes, and there was no evidence left of what the eyes had passed through. The gleet which remained after the last attack of gonorrhœa was then taken in hand by an expert and cured. The arthritis steadily improved after the last relapse of iridochoroiditis, and the patient eventually got well with no permanent joint defect.

Case IV.—A gentleman, aged twenty-five years, was brought under my care early in October, 1893. I saw him in consultation with his family physician, who gave me the following history: The patient was both hypermetropic and astigmatic, and had worn glasses in reading for several years. In the preceding April he had a severe attack of gonorrhœa, which lasted nearly three months. This was accompanied by acute arthritis of the right knee and left shoulder. At this time the eyes were not affected. He recovered from the urethritis and arthritis completely, but in the latter part of September he contracted a second attack of gonorrhœa, which resisted treatment as obstinately as the first attack. On the fourth day he was attacked by severe arthritis of both knees, and on the sixth day by an acute inflammation in the left ankle and wrist. On the eighth day after the appearance of the urethral discharge the right eye became inflamed, with severe pain, photophobia and lacrymation of a scalding character. I saw him first on October 9, two days later, and there were present all the symptoms of a severe iridochoroiditis; marked ciliary and conjunctival injection, chemosis of the ocular conjunctiva, cloudy aqueous humor, discolored and immovable iris, posterior synechiæ, and extensive exudation into the vitreous humor, marking all details of the fundus. Vision was reduced to $^{10}/_{200}$. and the tension was decidedly increased. There was excessive pain in the eye and head. At that time the left eye was intact, but on the next day signs of iritis appeared in this eye, and a severe iridochoroiditis rapidly developed. The grave nature of the attack was at once recognized. Three leeches were applied to each temple, hot fomentations were kept constantly applied to the eyes, a 2-per-cent. solution of cocaine and a 1-per-cent solution of atropine were instilled every two hours, and ten grains of sodium salicylate were ordered every hour, and this was directed to be continued as long as the stomach would bear it. On October 12 this drug was stopped on account of gastric disturbance. After twenty hours of the above treatment, the patient was almost entirely relieved of pain. Potassium iodide in twenty-grain doses was then ordered, and continued until October 28, when there was a recurrence of the inflammation in the eyes and knee-joints. The potash was stopped and the sodium was again administered in the same manner as at first, but on the second day I was obliged to discontinue it on account of gastric irritation. The treatment was then confined to the hot fomentations, atropine, and cocaine, with an occasional hypodermic injection of morphine to allay the severe pain. On November 11 the left eye was markedly improved, with a widely dilated iris and a hazy vitreous, and a vision of $^{20}/_{100}$: but in the right eye the ciliary injection was still quite marked, and there was considerable chemosis of the conjunctiva. The pupil, however, was wide, the adhesions having all been broken, the vitreous was much clearer, and all the details of the fundus were visible. By the 16th of November the vision was $^{20}/_{20}$, or normal, in each eye, the tension was normal, there was no pain, and the ciliary injection had nearly subsided. The knee-joints were nearly well, and the wrist and ankle were entirely well. Persistent treatment of the urethritis had been kept up, and the urethral discharge had also ceased.

Case V.—A gentleman, aged thirty-two years, came under my care for the first time on October 29, 1893. Three weeks before he had contracted gonorrhœa, and was treated by his family physician. For a week there was no complication except a mild orchitis, but on the eighth day the left shoulder and right knee became painful, and there was soon developed an acute arthritis in both joints, with great swelling and high fever. On the fourteenth day, after a violent attack of pain in the right parietal region and right eye, the eye became inflamed and vision was very rapidly impaired. When I saw him, on the fifteenth day, there was considerable swelling of the lids, some chemosis of the conjunctiva, marked conjunctival and ciliary injection, a hazy acqueous humor, discolored iris, posterior synechiæ, and a diffuse infiltration of the vitreous. with scarcely any reflex from the fundus. Vision was reduced to perception of light. The tension was normal. The iridochoroiditis had developed with great rapidity, which accounted for the marked impairment of vision. The same line of treatment was followed in this case as was employed in the first case. Ten grains of sodium salicylate were given every hour for nearly three days before signs of gastric irritation compelled the discontinuance of the drug. Hot fomentations were applied continually to the eye, atropine and cocaine were instilled every two hours, and three leeches were applied to the temple. For the first three days no visible effect was produced upon the intraocular inflammation, though the pain in the head, shoulder, and knee was decidedly relieved. After an interval of twenty-four hours, potassium iodide, in twenty-grain doses, was administered three times a day, combined with quinine. This relieved the pain in the eye very rapidly, but the potash soon disturbed the stomach, and I was forced to discontinue it. The local treatment was continued, and on the ninth day after I saw him, the treatment was changed to salicylate of cinchonidia, five grains every hour. The patient bore this very well and with excellent results. All acute inflammatory symptoms in the joints disappeared, the urethral discharge ceased, the aqueous and vitreous humors cleared up rapidly, and the ocular injection gradually diminished. Three weeks after I first saw him, all signs of iridochoroiditis had disappeared, the media were perfectly clear, and vision had risen to $^{20}/_{30}$ +. The other eye remained intact throughout.

47 West Thirty-sixth Street.

A CASE OF ANGINA PECTORIS, WITH AUTOPSY.

By BEVERLEY ROBINSON, M.D.,
NEW YORK.

I do not remember one instance of a case under my care of typical angina pectoris in which in private practice, I have been able to secure a good account of the autopsy. For that reason, and because of the interest of clinical aspects of the case, I am desirous of reading the following history, which in reality is more Dr. H. D. Arnold's (of Boston) than mine, and I am much indebted to his courtesy to be able to report it.

W. M., married, aged sixty-four years, American, business man, residing in Massachusetts, was seen by me in consultation with the local practitioner, at Westport, N. Y., last summer. At that time he was suffering from frequently recurring attacks of anginoid pains, which were distressing and threatening. Etiologically, a fairly manifest gouty condition in an individual who had worked hard and very continuously (except for a month's vacation in summer, latterly), and who was of highly-wrought nervous disposition, seemed to me to explain as best could be the origin and development of conditions which caused angina. There were no alcoholic habits, no syphilis, and no malaria. Moderate diet. Urine presumably free from sugar and albumin, but containing probably an excess of urates. Medication of different sorts, given by a careful and prominent physician of Boston, had failed to be of permanent use. Among these, strychnine and nitroglycerin had been evidently serviceable. Occasionally morphine was required by the mouth or hypodermically. The patient left Westport in bad shape. For his subsequent history and autopsy, which I now present, I am wholly indebted to Dr. H. D. Arnold.

Early in the afternoon of August 1, Mr. M—— had an attack of angina pectoris. A nearby physician was summoned, as I happened to be away. From all accounts this was the most severe and prolonged attack that he had had. Mrs. M—— had already given him the remedies she was accustomed to use, but it required more morphine, up to about one grain, before relief came. There was still more or less distress all the afternoon, and I was called in the evening. He was exhausted by his suffering all the afternoon. Pulse was irregular and intermittent. On the whole it was a weak pulse, although at times the tension became rather high. At such times he had distressed breathing and anginoid attacks. He had well-marked pulmonary œdema and cold extremities.

It was evident that the attacks of angina, of which he had had two or three daily, must be better controlled if he was liable to have such attacks as this one—not so much to prolong life, such as it was, as to prevent the terrific suffering. Morphine (which he had been getting frequently gr. ¼ to ½ at a time), in the doses used, was losing its effect, and he was wakeful, restless, and excited under its influence. The dosage was increased to gr. ½ as a minimum on morning of August 2. Under this he was quiet, slept at intervals, and had no attacks of real angina. His breathing at times became distressed, with high tension pulse, but he had no pain, and the tension yielded readily to nitroglycerin.

August 1 and August 2 passed thus quietly, with improvement in his cardiac condition and general strength. August 3 the morphine was omitted and cathartics given, his bowels moved without any bad attacks, and then morphine was to be given enough to secure a night's rest. This day (August 3) he developed for the first time an acute mania. He had been excitable and suspicious on August 1, but the condition was not fully developed until August 3. It took gr. i of morphine at a dose to affect him at all, and its effect soon wore off. August 4 it took grs. ii at a dose. In the meantime he was violent at times, restraint being needed twice; he refused medicine and food and could not be kept under the influence of morphine because it could not be given. August 4 he was losing strength and was wildly insane. In one violent attack he had to be restrained, and we held him long enough to inject morphine. It nearly killed him (the struggle), but this morphine, with some given in a peach and in whiskey, finally quieted him, and after that he was not allowed to come out from its influence. Grs. ii were used subcutaneously, and was renewed as often as its force weakened. He was finally under its influence at one o'clock P.M. His pulse was very weak, pulmonary œdema, cyanosis, cold extremities, and he was evidently failing rapidly. He lived until 5 P.M. Notwithstanding the free use of morphine he was awake and talked deliriously from 3 to 4 o'clock, though not violent. For the last hour he had Cheyne-Stokes' respiration, becoming very cyanosed, and struggled for air at the beginning of the cyanosis, so that ether became necessary, and then chloroform to keep him from suffering. He was mildly under anæsthesia for the last three-quarter hour of his life.

Throughout all this his heart maintained its work in a wonderful way, and I have mentioned what he went through in some detail that you might better understand the cardiac endurance. I naturally expected a sudden cardiac collapse or failure, but the failure was very gradual, and to the very last the heart action outlasted the respiration. Sudden and extreme cardiac weakness was shown only once. On morning of August 4, when, in a time of extreme violence, it took three persons to hold him quiet enough to give a subcutaneous injection of morphine. He struggled until he was almost black in the face and practically pulseless and we released him. Much to my surprise he recuperated.

This good showing on the part of his heart is explained by the autopsy findings. The heart was considerably dilated (though that is not mentioned in the report) and much hypertrophied, although the ventricular wall is not as much increased in thickness as is frequently the case. The weight, 690 grams (well distributed through the whole heart), tells the story. The cardiac muscle was of remarkably good quality. The coronary arteries, although uniformly affected by arteriosclerosis, were of large caliber and patent throughout, except near the end of a small branch. Their openings from the aorta were large. We had then a large, well-nourished, strong heart. Moreover, the angina was not due (as so often) to localized sclerosis and obstruction to the lumen of the coronary arteries.

The changes in the mitral valve were due to the same sclerotic changes, and while there was some mitral regurgitation, it played but a minor part in the case.

The important thing was the general arteriosclerosis. I have never seen a case in which it was so generally distributed, or where it was so uniform throughout the entire arterial wall. There were very few of the ordinary patches of sclerosis, and these were at an early stage, but the wall was uniformly and smoothly thickened. The walls were still elastic, though the elacticity was diminished.

This general arteriosclerosis, of course, explains the cardiac hypertrophy and dilation. It does not, however, explain in itself the attacks of angina—that heart could maintain the circulation without distress under all ordinary circumstances in spite of the arteriosclerosis. The attacks were not necessarily dependent on over-exertion. They were, at least usually in those seen by me, accompanied by high tension of the pulse. This is, of course, a vasomotor change, and is accompanied by a great increase of the cardiac work—an increase sufficient to embarrass even that strong heart when added to the usual burden of the arteriosclerosis. Possibly, too, the vasomotor spasm also affected the coronary arteries, and, by temporarily diminishing the nutrition of the myocardium, added to the result. But if there was anything of this sort it did not persist long enough to permanently affect the nutrition of the myocardium. It seems to me, then, that the cause of his attacks lay in the nervous mechanism of the vasomotor system and not in the circulatory system itself. Is it possible, too, that the vasomotor system bears in this case an etiological relation to the arteriosclerosis? We have no interstitial kidney, and not enough alcohol, lead or other toxic substance, nor syphilis, as far as I know the history. His intense, excitable, nervous temperament is suggestive in considering a nervous etiology for his whole trouble.

The only cerebral lesion of any account (beyond arteriosclerosis, which, by the way, did not occlude any vessels) was a moderate leptomeningitis. While I have seen this in some cases of insanity, I have failed to understand its relation, if any. In Mr. M.'s case it was an old affair, and hardly seems to have connection with his mental derangement, unless that is of much longer duration than I was informed.

In my answer to Dr. Arnold's first letter I directed attention to the following points:

1. Possible gouty origin of disease.
2. Hydrothorax as evidence of cardiac insufficiency (shown at autopsy).
3. Objections to use of morphine, especially in large, repeated doses, in analogous cases, viz., locking up secretory elimination.

I agree substantially with Dr. Arnold about many aspects of the case, and consider his report admirable in most particulars.

I present herewith autopsy by Dr. W. R. Brinckerhoff, assistant pathologist at Boston City Hospital.

In a second and later letter to me Dr. Arnold recognized that "the morphine was undesirable whilst allaying anginal seizures, in causing, in part, an acute maniacal attack." Upon further inquiry it was found that unusual tolerance for morphine was explained by history of morphine habit some years previously and by use of other hypnotics since. It was evident that when other drugs had been pushed to their limit without much relief, morphine was the only effective one.

It was also shown, apparently, according to Dr. Arnold, that the morphine did not cause accumulation of locked-up material sufficient to produce appreciable effect.

In a third and last letter to me, Dr. Arnold thinks that through later information received by him, a gouty condition in Mr. M.'s case is pretty definitely established. In the family history it is noted that one brother died of angina pectoris at fifty-two years. In the previous history of the patient it is noted that for twenty years he had had "anginoid" attacks, and his pulse had been irregular and intermittent. On the other hand, he had no dyspnœa or palpitation on severe exertion and no cough. About two years ago the attacks became more severe and were those of typical "angina." Patient had been mentally peculiar for many years and at times temporarily mentally unbalanced. This is accounted for, perhaps, by old leptomeningitis shown at autopsy.

In conclusion, Dr. Arnold writes: "This previous history and long duration of 'anginoid' attacks was of special interest to me. In the same patient we have had what are ordinarily called 'anginoid' attacks and 'true angina pectoris;' we have not the common organic troubles in the heart; we have arteriosclerosis of a peculiar type; we have a toxæmia ('gouty'?)—have we not a connecting link in the nervous system, possibly the vasomotor? This is one of the cases that show there is no sharp line between 'true' and 'false' angina. Is angina anything but a cardiac symptom anyway?"

After carefully considering the foregoing from every aspect, I regard the repeated attacks of angina as probably of so-called "uræmic origin," and the final maniacal seizure as being of this origin also, accentuated and made worse by repeated large doses of morphine. Of course, the general arteriofibrosis was the anatomical feature of the case, which rendered the uræmic symptoms possible and ultimately fatal. The mere fact that the kidneys showed possibly only passive congestion, does not, to my mind, render the attacks different, essentially, from what they would have been with more advanced structural changes in these organs.

I have no repeated or accurate examinations of urine to fall back upon to guide me as to what precisely the kidneys were doing functionally. Still, even presuming that the quantity of urinary solids eliminated at particular periods, or usually seemed sufficient, and that the urine contained neither albumin nor sugar nor hyaline, nor granular casts, my medical judgment of the case would not be materially altered.

That the poisons included in the term "uræmia" may produce at times neuralgia or neuritis, affecting the cardiac plexus, does not seem improbable, reasoning by analogy with facts familiar to practitioners of medicine.

The following is the report of the autopsy by Dr. Walter R. Brinkerhoff, Assistant Pathologist to the Boston City Hospital:

Autopsy, August 6, 1902.—Body of a well-developed and well-nourished white man. Age, sixty-four years. Peritoneal cavity—surface normal. Intestines of a deep purplish red color. Appendix normal. Mesenteric lymph nodes normal. Diaphragm at normal height.

Pleural Cavities.—Each contains about a liter of clear, straw-colored fluid. On the left side the apex of the lung is bound to the chest wall by firm fibrous adhesions.

Right pleura normal.

Pericardial Cavity.—Surface normal. Contains about 100 c.c. of clear amber-colored fluid.

Heart, weight 690 grams. Tricuspid and pulmonary valves normal. Pulmonary artery opened *in situ*, contains post-mortem clot. Foramen ovale, still patent, by a small opening 4 mm. across, which passes obliquely through the interauricular septum in such wise as to be guarded on either side by a valve-like flap. Left auricle presents granular, red, friable masses, entangled in the musculi pectinati of the auricular appendage. Mitral valve is considerably thickened, its chordæ tendineæ shortened and thickened, but its surface is smooth. Aortic valve presents thickening of the cusps, but no roughening. The wall of the left ventricle is much thickened, but the consistency, color, and markings are normal. The wall of the right ventricle is also considerably thickened. The coronary arteries are thickened evenly throughout, their linings are smooth, and the lumen stands open on section, except in a small branch of the left coronary artery, situated in the auriculoventricular groove. This vessel contains a small patch of sclerosis, which is circumferential and almost occludes the lumen at that point. The heart muscle in relation with this branch is normal on section.

The aorta shows diffuse thickening, with here and there an elevated yellow plaque.

Measurements of Heart.—Tricuspid valve, 13.5 cm.; pulmonary valve, 9.0 cm.; mitral valve at ring, 11 cm.; mitral valve at edge, 9 cm.; aortic valve, 8.5 cm.; wall of left ventricle, 1.5 cm.; wall of right ventricle, .7 cm.

Average normal measurements are: Tricuspid valve, 12 cm.; pulmonary valve, 9 cm.; mitral valve, 10 cm.; aortic valve, 8 cm.; wall of left ventricle, 1.1 cm.; wall of right ventricle, .6 cm.

Lungs.—Normal on inspection and palpation.

Spleen, weight 330 grams. Surface smooth and of a deep-red purple. On section, trabeculæ are prominent, spleen substance comparatively dry. Malpighian bodies not visible.

Pancreas normal.

Gastrointestinal Tract.—Much congested, otherwise normal on inspection.

Liver.—Normal size, color, and consistency. On section the cut surface shows in places, a suggestion of the "nutmeg" markings. Elsewhere the centers of the lobules are pale.

Kidneys.—Weight of one, 290 grams. Capsule strips readily from a smooth deep-red purple surface. On section the cortex and pyramids are deep-red purple, the markings are distinct, and the glomeruli present as red pin-point elevations.

Adrenals normal.

Genital organs not examined.

Brain.—Dura very adherent, and contains calcified plaques at the site of the Pachyonian granulations. Dura and pia adherent at many points.

Pia markedly opaque, particularly along the vessels over the vertex. No excess of fluid in membranes or in ventricles. On section, brain substance normal texture, but rather moist. Vessels at base evenly thickened, but with smooth intima, and only an occasional small patch of early sclerosis.

Anatomical Diagnosis.—Hypertrophy of heart; chronic aortic and mitral endocarditis (slight); general diffuse arteriosclerosis; chronic passive congestion of liver (slight), spleen, kidney, and intestine; hydrothorax; slight chronic leptomeningitis.

Microscopic Description.—Aorta—In places there is beginning atheroma, shown by degeneration and very small and scattered are as of lime-salt infiltration.

Spleen.—Much congestion of pulp. Otherwise not notable.

Liver.—Some atrophy of liver cells about central vein, with dilatation of capillaries and deposition of brown pigment in the liver cells. Other portions of lobule normal.

Kidney.—Marked injection of the vessels. Otherwise not notable.

A Case of Abdominal Sarcoma Benefited by Arsenic.—W. S. Yates describes a case in which—the tumor, from its situation, being inoperable—arsenic was resorted to in order to give some relief to the patient. He started with five-drop doses of Fowler's solution, and rapidly pushed it up to twenty-five drops t. i. d., when the limits of tolerance were reached, and he had to go back to fifteen drops, which were continued for about three months. During this time the pain entirely disappeared and the patient could sleep naturally. The neoplasm shrunk in size fully three-fourths. For four months the patient was lost to sight and took no medicine. The tumor was again enlarging, and had attained at least one-half its former size. The patient is again on arsenic in increasing doses, and the author hopes to again get improvement.—*The Wichita Medical Journal.*

A CASE OF TYPHOID SPINE.*

By LEONARD W. ELY, M.D.,
NEW YORK.
ORTHOPEDIC SURGEON TO THE ROOSEVELT HOSPITAL DISPENSARY.

In the *Boston Medical and Surgical Journal* of June 26, 1902, Dr. Frederick T. Lord gives a summary and analysis of twenty-six cases of typhoid spine since Gibney reported his first cases in 1889, including all those reported up to January 1, 1902. I have been able to find three more cases reported since then. It would appear that the disease is not so rare as was thought, and that the symptoms present a fair degree of uniformity. I have had exceptional facilities for observing the case I am about to report:

The patient, a physician, thirty-three years old, was admitted to the service of Dr. James at the Roosevelt Hospital on January 18, 1902, evidently at the end of the first week of a severe case of typhoid fever. A history was obtained of rheumatism. The attack was complicated by pneumonia and pleurisy. When, about six weeks later, the patient began to sit up, a weakness of his back was observed—he was compelled to "climb up on his thighs" after sitting. He was discharged from the hospital on March 10, and returned to his home. The weakness in his back continued, but was disregarded, and was soon made much worse by an attempt to stoop over, and again by the effort to trim a plaster-of-paris jacket. From this the real symptoms seem to date. A lateral curvature and a stiffness of the lumbar spine were observed, with a moderate amount of pain and great difficulty in standing erect.

On March 23 the patient, after an exposure to cold, had a severe chill, and again took to his bed, this time with a pneumonia of the entire left lung. The pneumonia was complicated by pleurisy with effusion. Fifty-two ounces of fluid were drawn from the left pleural sac. Repeated examinations of the sputum and inoculations of guinea-pigs failed to reveal the presence of tubercle bacilli. The temperature subsided by lysis, and the resolution of the pneumonia was very slow.

During the pneumonia the spinal symptoms were unnoticed, but when, about three weeks after the beginning of the disease, the patient began to go about, the lateral curvature was quite marked, and was accompanied, as before, by stiffness, weakness, and considerable lumbar pain. There was neither at this time nor at any subsequent period sensitiveness to pressure of any part of the spine. Inasmuch as pain, evidently due to pleurisy, was present in the front of the chest, the back symptoms were ascribed to the same cause, and the patient was allowed to depart for Southern California on May 3, at his own urgent request, though with some misgivings on the part of his medical advisers.

In California the pulmonary and pleural symptoms gradually subsided; not so those referable to the spine. These persisted in spite of massage and heat, and very slowly became more severe. The stiffness, weakness, and pain were increased by exertion, and were especially marked on starting to walk after sitting—the patient would stand for some seconds with his hands on his back trying to straighten up. Sneezing was very painful.

On June 8 the lumbar symptoms were aggravated by the attempt to use some Wolff's bottles, and for several nights thereafter the patient complained, on retiring, of a throbbing pain in his back. On June 11 the attempt was renewed, and, shortly afterward, in rising from his chair, the patient was seized with a cramp in the left lumbar region. This cramp was repeated several times during the evening, but subsided soon after retiring. The Pacquelin cautery was applied, but caused so severe a return of the spasm that it was not again used during the disease. The next morning the spasm reappeared with such intensity when the patient arose that he was forced immediately to go back to bed. The same thing occurred on the following morning. The patient went back to bed, because he recognized his absolute inability to walk. Rubber strapping was applied and affected the symptoms not at all.

---

*Read before the Orthopedic Section of the New York Academy of Medicine, November 21, 1902.

From this time no attempt was made by the patient to rise from his bed. One or two quite severe attacks of pain were experienced during the next few days, but disappeared shortly after the administration of a quarter grain of morphine by the mouth. The urine was analyzed. It was strongly acid, specific gravity 1,030, and contained a few uric-acid, and many oxalate-of-lime, crystals.

Stiffness and pain persisted for three days, and, then, in the evening, while turning over in bed, the patient was seized with a terrible muscular spasm in the left lumbar region. The spasms were tonic in character, lasting about thirty seconds, gradually relaxing, and with an interval of about the same length. The pain was excruciating, and was not affected in the slightest degree by a quarter of a grain of morphine by the mouth and a quarter of a grain hypodermatically. After it had lasted for about half an hour, the patient was chloroformed to complete narcosis. He was chloroformed several times that night, and once or twice daily for three days thereafter. During one of these periods of narcosis, the rubber strapping was removed. It was necessary to chloroform the patient to put him on the bed-pan or even to turn him in bed. Changing the bed linen was out of the question. Morphine was of little use in the spasmodic pain, but the chloroform caused a rapid, irregular, and intermittent pulse, and was discontinued on that account. The temperature during all this time had ranged between 97° and 100° F. by the mouth, and the pulse had not gone above 80° under ordinary circumstances.

The pain now shifted to the right lumbar region. Besides the stiffness and a moderate amount of constant pain, the spasmodic attacks were fairly frequent, though never so severe as the initial paroxysm. The ordinary pain was much lessened by morphine, three-quarters of a grain to one grain daily.

Examination at this time, according to data furnished by Dr. Barlow of Los Angeles: Extreme prostration, abdomen distended with gas, patellar reflexes greatly exaggerated. Plantar reflexes produce contractions of the quadriceps extensor. No ankle clonus, no Babinski symptom. Intermittent twitchings distinctly visible of the muscles of the thigh and of the abdomen, especially of the recti. Muscles not tender, except on deep pressure. Sensation perfect everywhere, including senses of position, pain, and temperature. No paralysis, but weakness of the lower limbs and fear of movement on account of producing spasm.

Urine, alkaline. Specific gravity, 1,022. 50 ounces in twenty-four hours. 24 grams of urea. Microscopical, negative.

Blood count: red cells, 6,000,000; leucocytes, 6,000.

Chloral, 30 grains, and extract of digitalis, 3 minims, per rectum, were without effect. Hyoscine hydrobromate seemed to lessen the spasm, but was abandoned on account of its apparent effect on the heart. Hyoscyamine was useless.

On June 25 the location of the pain had changed to the abdomen. The spasmodic contractions of the abdominal muscles during the paroxysms could be felt with the hand. The disability was now so great that the patient was only moved on his side occasionally, in order to cleanse and powder his back, and to change the bed clothes. The next day, June 26, the pain returned in the back. Severe spasms occurred, in which the head was drawn back and thighs were flexed. The lower extremities were cold and clammy.

On the morning of July 1, after a very bad night, the patient awakened, feeling chilly. The temperature shortly afterward was 104.2°, the pulse 120, respiration 25. Nausea and explosive vomiting occurred twice during the day, the patient being in a semi-comatose state, but easily awakened, and then the temperature slowly sank to 100.4°, and the pulse to 96 at 7 P.M. They fell to normal on the following day. The temperature from now on ranged between 97.1° and 99.8°, on two occasions running to 100.2°. I am told by one of the nurses that the attacks of pain were usually preceded by a rise in temperature, and that their occurrence could often be prognosticated.

The spasmodic attacks continued at intervals until July 27. Their location was in the right side of the back and abdomen, and in the right groin and hip. They occurred almost invariably at night. When they were very severe, ether was used, when milder, morphine.

From about the middle of July until the middle of August the patient suffered from a pain which is worthy of note—the so-called "starting pain." Upon falling asleep he would immediately awake with a severe pain in his groin, and usually with a cry. This would sometimes be repeated three or four times, unless morphine was used. In the end this drug would almost always be necessary.

On August 5 the patient sat up for a few seconds, with assistance. A day or two later a gas-pipe, canvas-covered frame was made for him, and he was carried about on this. On August 14 he stood up. On August 16 the last dose of morphine was given.

From this date on convalescence was slow, and easily interrupted by the slightest over-exertion. On one occasion it was necessary to confine the patient to his bed again for ten days, on account of the return of the pain and stiffness, and following another rise of temperature to 101.4°.

On September 22 a Taylor brace was applied. The improvement now became more marked. The most persistent symptom was pain and stiffness in the right groin, especially on waking in the morning.

On October 13 the patient left California, and on the 18th was seen in New York by Dr. Whitman. The only objective sign of disease at that time was a stiffness and limitation of motion in the lumbar spine. This was much less three weeks later.

The patient now goes about wearing his brace. He can walk a moderate distance, and attend to the lighter duties of his practice.

A few facts may be mentioned in addition:

1. No doubt is possible of the diagnosis of typhoid fever. It was a perfectly clear case, with the usual abdominal symptoms, the roseola and a Widal reaction of 1-100.

2. The urine during the acute attacks of pain was scanty and concentrated. In fact, during all the active period of the disease a small amount of urine was passed, ranging in the twenty-four hours from 18½-30 or 40 ounces, rarely up to 52 or 53.

3. While any motion of the trunk or lower

extremities was often painful, and while great weakness was present, there was no paralysis.

4. The pains were such as we are apt to hear of as accompanying disease of bone. They were evidently "referred" pains. The painful area was never sensitive to pressure.

5. There was a distinct history of a trauma. While the back after the typhoid was always weak and perhaps slightly painful, the real symptoms of the disease were first apparent after a strain, and by a strain were on three different occasions aggravated.

To our knowledge of the pathology of typhoid spine, a little has been added since Gibney reported his first case. No case has ever come to autopsy, but nine have been accompanied by a kyphosis, showing a probable destructive lesion. It is quite possible that there is the same analogy between typhoid spine and Potts' disease as there is between a typhoid pneumonia and a tuberculous pneumonia —one tends to an acute course and a comparatively rapid recovery, and the other to a more chronic course and a breaking down of tissue. We feel fairly certain that it is an osteitis. It is probably combined with a periosteitis. Indeed, Quincke reports two cases much alike, builds up a more or less complete pathology, and calls the disease, with true German precision, "spondylitis typhosa." Könitzer has heard of no other cases than Quincke's, though the latter in his article quotes Gibney and Osler, and follows his lead with the name. He cannot, however, quite fit his case to Quincke's exact description. The other three Germans who have reported cases, Kühn, Herz, and Neisser, use the same nomenclature, and are guilty of the same bad manners.

In the case which I have reported, it is reasonable to assume an inflammation that, affecting first one region, subsided there and then attacked adjacent regions of the spine. It is not unlikely that a neuritis was caused by the inflammation of the bone and of the periosteum, and that one or more of the spinal articulations were involved.

This is generally considered to be the pathology of typhoid spine. The only writer of note who takes an entirely different stand, based on cases he has observed, is Osler, who thinks it is a neurosis, and reports six cases. Case 1 was seen some time after the acute trouble would seem to have subsided, remained in the hospital one week, and had slight pain in his legs and back. This resembles very slightly what we understand as typhoid spine. Case 2 was seen two months after the beginning of the trouble. This was evidently hysteria. Whether or not the patient had had typhoid spine we are unable to say. Cases 3 and 4 were probably mild cases. Case 5 was possibly typhoid spine, and case 6 a mild case. Osler finds that the disease yields promptly to treatment by massage, electricity, and general tonics, while other observers say that it is apt to last somewhat more than a year. In regard to prognosis, Osler delivers this somewhat Delphic utterance: "The patients get promptly well or improve with great rapidity . . . It is true it sometimes takes weeks or months before a complete cure is effected." (*Johns Hopkins Hospital Bulletin*, No. 125, p. 265). It is quite evident that Dr. Osler has forced some of his cases into a category where they do not belong.

Lovett and Withington's case had stigmata of hysteria, and was regarded by them as a post-typhoid neurosis until the kyphosis appeared. Taylor's case had stigmata of hysteria, but it also had a kyphosis. Our patient was considered hysterical by his nurses, and by them was given hypodermics of water, but Dr. Brainerd, a nerve specialist of Los Angeles, could find no evidences about him of hysteria.

The increased knee-jerks in our case could be due to slight pressure above the reflex arc, or to the increased nervous irritability following typhoid. In some of the cases described the knee-jerks have been diminished.

No cause is known for the disease other than the presence of the typhoid bacilli. Including the case I have reported, twenty-six out of thirty have been in males. Only six of Lord's collection of cases gave a history of a trauma, yet the impression that one gets in reading up the histories is that the patients were accustomed to use their muscles freely. Often the occupation is not given, but two were blacksmiths, one a peddler, one played tennis after his typhoid, one skated, one was a physician who had been an instructor in physical culture, one a servant, one a coppersmith, one a ship's boy, and in this case the patient was addicted to violent muscular exercise.

The chief symptoms are pain, weakness, stiffness, disability, and muscular spasm. The pain may be in the back, groin, abdomen, hip, or thigh. Local tenderness to pressure has been observed in eighteen of the reported cases. Probably if the posterior portion of the spine is affected, tenderness to pressure will be observed. The symptoms are much like those of lumbar Potts, but they are more acute, and have the history of a previous typhoid fever. In our patient there was a strong suspicion of a tuberculous lesion, on account of the preceding pneumonia with slow resolution, and because of tuberculosis in the patient's family.

Lateral curvature has been observed in three cases, including the one described above. Taylor's case had the peculiar rhythmic contractions of the abdominal muscles. Moorehouse mentions the muscular twitchings in one of his cases, and says a suspicion of meningitis was awakened. One of Neisser's patients had twitching in his legs. A diagnosis of meningitis was at one time made in our case.

At some time in the course of most of the cases in which the symptom is mentioned, the temperature runs up quite high. In some it stays up for a long time. Neisser makes prolonged fever one of three cardinal symptoms of typhoid spine, but a cardinal symptom based on three or four cases is not of much value.

The diagnosis, with our present knowledge, may at first be very difficult, and we are not yet able to shut out any cases with certainty, but any severe lumbago following typhoid fever should be viewed with extreme suspicion, and should be treated as typhoid spine.

If we have any spasmodic attacks of pain, or evidences of muscular spasm, or limitation of motion, especially if fever is present, we may feel fairly certain of our ground.

Prognosis.—The prognosis is good. All the patients recover, though two or three instances of relapse are on record.

Treatment.—All authorities except Osler agree on the treatment—rest. If our patient had kept quiet he would not have been exposed to injury. We know that the several strains made his trouble worse, but whether or not he would have escaped the severe pain altogether if he had kept quiet, we can only surmise.

The more complete the rest is, the better. The recumbent posture is best, perhaps, in a plaster-of-paris bed or on a gas-pipe frame. Later, a spinal brace or a plaster-of-paris jacket may be applied. Massage, electricity, heat, or cold may be useful. The Pacquelin cautery has been recommended. If the pain is very severe, it ought to be stilled, even if an anæsthetic be necessary.

The writer acknowledges his indebtedness, for information included in this article, to Drs. James and Braunlich of New York; Wynne, Tyler, and Power of Redlands; Barlow, Brainerd, and Cole of Los Angeles; and Sherman of San Francisco, Cal. He considers it right to say that he himself was the patient, for, while this fact may lend a certain realistic coloring to the description, it may, perhaps, be thought to detract from its scientific value.

451 West End Avenue.

A STUDY OF THE INDICATION FOR NEPHROPEXY.*

By AUGUSTIN H. GOELET, M.D.,
NEW YORK.
PROFESSOR OF GYNECOLOGY IN THE NEW YORK SCHOOL OF MEDICINE; GYNECOLOGICAL SURGEON TO THE METROPOLITAN HOSPITAL FOR WOMEN AND CHILDREN, ETC.

Bear with me until you have heard me through if I say at the outset that the indication for fixation of the kidney is prolapse to the third degree or beyond; that is, when the whole organ is found prolapsed below the last rib in front. I make this statement without qualification, except absolute contraindication to operation. Even where there is apparent absence of symptoms or external evidence that the prolapse is causing disturbance, the contention holds good, because the kidney is necessarily crippled in consequence of the prolapse.

In order to be able to give the views of others upon the indication for nephropexy, I wrote to a number of gentlemen, and received the following replies:

Howard A. Kelly of Baltimore writes: "Nephropexy has come to be one of the commonest operations I have performed. I base the indication for the operation upon the symptomatology and upon the displacement of the kidney and upon an injection of the kidney, bringing on an artificial attack of colic, definitely proving that the symptoms complained of come from the displaced kidney. I operate in cases of displacement in which the upper pole can be palpated and in which there are attacks of intermittent pain referred to the right or left side. I am very hesitant about operating upon lesser grades of displacement, or where the symptoms are rather vague and the patient complains rather of ill health associated with digestive disturbances."

Robert T. Morris of New York writes: "Nephropexy is not indicated in cases of true floating kidney, with long mesonephron, or in cases of acquired loose kidney, provided that there is no nephritis present, and provided that the pressure symptoms and reflex nervous symptoms are controllable by the application of a straight front corset, laced from below.

"In cases with nephritis that is apparently dependent upon vascular interference due to the position of the kidney, nephropexy and decapsulation of the kidney are indicated even in cases in which artificial support gives relief from pressure symptoms and reflex nervous symptoms.

"Nephropexy is a futile resource in cases with general enteroptosis unless the suspensory ligaments of the liver are shortened at the same time, to prevent that viscus from pressing a kidney away from its anchorage. There is usually in such cases a diastasis of the rectus abdominis muscles which requires repair, before nephropexy is indicated.

"In general, nephropexy is indicated in a large proportion of all of the cases of floating kidney, and in practically all of that group of cases of acquired loose kidney in which the excursions of the kidney cannot be controlled by the corset sufficiently to give relief from the pressure symptoms, and the symptoms of reflex nervous disturbance."

Charles P. Noble of Philadelphia writes: "In reference to the indications for operation I would make the following:

"Careful discrimination in diagnosis, in order to separate cases in which movable kidney is a coincidence in a case of neurosis from those in which it is the cause of local and reflex symptoms.

"Resort to the rest cure for cases of slightly movable kidney, especially in young women.

"The employment of symptomatic treatment in cases in which the relation between the movable kidney and the nervous symptoms present is uncertain. Nephrorrhaphy should be employed in these cases only after nonoperative measures have failed to afford relief.

"The immediate resort to operation in those cases in which local symptoms, such as pain, sense of weight, or symptoms of strangulation, are present, and when the examination of the urine shows indication of congestion of the kidney, such as the presence of hyaline casts or albumin."

Henry Morris of London in the *Lancet* for November 30, 1901, gives the indications for nephropexy as follows:

"1. When movable kidney is associated with enteroptosis no operation should be done unless it is evident that the more serious symptoms are due to the movable kidney alone.

"2. When movable kidney is complicated by movable liver the same rule should be followed as in general enteroptosis.

"3. When the movable kidney occurs in a hysterical or neurasthenic subject palliative means should be tried before resorting to operation.

"4. For uncomplicated movable or floating kidney in which the principal symptoms are pain and gastrointestinal troubles the operation may be confidently advised and carried out without any previous trials of belts or of rest.

"5. When renal crises are a feature of the case, nephropexy ought to be strongly urged because of the constant risk of hydronephrosis and recurring pain.

"6. When a movable kidney gives rise to no inconvenience, an operation ought not to be thought of and belt need not be worn."

Continuing, he says:

"It is chiefly in the rare cases in which movable kidney is associated with enteroptosis that belts are of any real value. My experience leads me to attach no value to rest in the recumbent position. In several instances in which I have operated with most gratifying results the patients have kept the recumbent position for six or nine months before operation without the least improvement from it, all of their symptoms returning immediately after getting about again."

I would like it understood here that I employ the term "prolapse of the kidney" to designate those degrees of descent of the organ where the upper pole can be palpated below the border of the last rib in front. So-called prolapse of the second and third degree, where only the lower pole and half of the organ respectively may be palpated at the same point upon deep inspiration, might be more properly designated loose kidney or movable kidney, and is, no doubt, the condition referred to by most authors as "movable kidney." These latter are the cases that are benefited by belts or corsets.

There are three principal indications to be found for fixing the kidney:

1. The symptoms of inconvenience it produces.
2. The influence it may exert in producing or maintaining disease of the female pelvic organs.
3. Its influence in causing disease of the kidney itself.

(1) The symptoms produced by prolapse of the kidney appear to be viewed in different light by different observers and indifferently by others. Though they have been attributed by some to other causes which may co-exist, they are frequently relieved temporarily by artificial support of the kidney and permanently by fixing this organ, if the operation is resorted to early enough.

The disturbance that may be produced by prolapse of the kidney depends much upon the condition and environment of the patient. If the health is already impaired, its influence is more pronounced and its evil effect is more noticeable. Then, again, if the patient is obliged to earn her living, or if her social or domestic requirements compel her to be actively employed and much upon her feet, she will suffer much inconvenience from it. If she wears corsets in the usual manner, the symptoms will be more pronounced, whereas, if she be one of the fortunate few who do not wear corsets, nor even wear clothing tight about the waist, she may suffer little inconvenience for a time. But while such omission of the requirement of fashion may remove one source of irritation of a kidney that is prolapsed, it does not obviate it entirely, and in time if the condition is neglected the influence of the prolapse will be manifested in an unmistakable manner.

---

*Read at the nineteenth annual meeting of the New York State Medical Association, October 20 and 23, 1902.

Not only does prolapse of the kidney give rise to symptoms that are readily recognized by those who have given the subject careful attention, but it sometimes causes marked impairment of the health of the patient, and at times considerable loss of flesh. The most frequent and most distressing symptoms are those which point to derangement of the digestive apparatus and of the genitourinary organs, with fatigue and general depression following exertion of any kind in the erect position. Though the symptoms may not be always severe or unbearable, they frequently cause chronic invalidism, in which may be found sufficient indication for operation.

There can be no good reason offered for delaying an operation that involves no risk because the symptoms which the condition gives rise to are not unbearable, or until the health of the patient becomes so much impaired that recovery is doubtful or impossible.

More serious operations are done every day for conditions in the pelvis which cause far less inconvenience than does prolapse of the kidney.

(2) In a paper presented at the last session of the American Medical Association in the Section on Diseases of Women,* I pointed out that the prolapsed kidney, by interfering with the return circulation from the pelvis, may cause or maintain disease of the female pelvic organs. This is brought about chiefly by pressure of the prolapsed kidney upon the ovarian vein in its course along the spine. When the kidney descends, its lower pole swings inward toward the spine and overlaps the ovarian vein and ureter. Therefore, when the abdomen is compressed by corsets or clothing at the waist, the kidney is forced backward and compresses the ovarian vein between it and the solid structure of the back. Thus, during the greater part of the twenty-four hours when the patient is on her feet, the return circulation from the pelvis is interfered with and pelvic congestion is the result. It will be unnecessary to detail here the conditions in the pelvis that may be produced or maintained in this manner by prolapse of the kidney. They have been set forth with sufficient fulness in the paper referred to.

The association of pelvic disease with prolapse of the kidney cannot be a coincidence, as has been contended by some who have opposed my views on this point, because, *first*, it is too frequent; *second*, the explanation of cause and effect is rational; and, *third*, these conditions in the pelvis are cured by fixing the kidneys in some instances in which measures directed only to the pelvic condition have previously failed.

If the above premise is correct, the co-existence of pelvic disease may be considered a strong indication for fixing the kidney when it is prolapsed.

(3) We come now to the third and most important indication for nephropexy, namely, the condition of the kidney itself produced by the prolapse. It will be admitted that we have in prolapse a condition which interferes with the function of the organ, produces congestion, and frequently retards or obstructs the outflow of excreted urine—a condition which, if left uncorrected, must eventually lead to inflammation of the organ or degeneration of its structure. Henry Morris, in his work on "Surgical Diseases of the Kidney," referring to the prognosis of movable kidney, says: "Besides the tendency of the mobility to increase, there is also a tendency for the kidney itself to undergo degenerative or inflammatory lesions. . . . Intermittent hydronephrosis due to repetitions of kinking or curvature of the ureter, intestinal obstruction due to compression of the bowel by the displaced kidney, and later, a pyelonephritis and pyonephrosis from septic infection of the dilated renal pelvis are complications which are occasionally provoked by movable kidney."

My own observations upon the operating table convince me that these kidneys are never in a healthy or normal condition after the prolapse has progressed to the third degree. I have already drawn attention* to the marked difference of the two kidneys in the same subject when one is prolapsed to the third degree or beyond and the other is only in the second degree of prolapse when the operation has been done on both kidneys at the same time. These observations, more than anything else, have convinced me of the advisability of early operation if the whole of the organ is below the level of the last rib in front when the patient is on her feet. As a rule, I fix the other kidney at the same time if it is found in the second degree of prolapse; that is, when half of the organ descends to the lower border of the last rib in front, on deep inspiration when the patient is in the erect position. This is done to avoid the necessity of a second operation later, which would inevitably be required.

It is my custom to submit the urine of every patient with prolapse of the kidney to careful microscopical examination to ascertain definitely just how much injury the kidney has sustained as a result of the displacement. These examinations are repeated at intervals until operation is decided upon to ascertain the progress of the disease. After operation the urine is also submitted to careful microscopical examination to note the improvement that follows operation. I have selected ten cases, taken at random from among those that have consulted me during the past month and in which I have advised operation, and I append herewith the result. Some of these cases have already been operated upon.

In every case except two there has been found evidence of either marked irritation or inflammation of the ureter, pelvis, or kidneys, and in many of them an associated cystitis. In one case only (No. 7) was there evidence of only moderate inflammation of the pelvis of the kidney. This patient who had the right kidney prolapsed to the third degree is a single woman, thirty years of age, had not worn corsets since she was seventeen years old, and has never worn her clothing tight, yet for the past few years she has had pain in the region of the kidney, with marked disturbance of the digestive apparatus, occurring every few weeks, precipitated by some unusual exertion. I operated upon her recently, and found the kidney enlarged, congested, and adherent to the fatty capsule, showing evidence of perinephritic inflammation of long standing.

It will thus be seen that the kidney is always in a crippled condition as a result of the prolapse, and we are not justified in disregarding it or in delaying operation until the health of the patient becomes seriously impaired or the kidney is irreparably

---

Journal of the American Medical Association of August 23, 1902, p. 4177.

*"Technique of Fixation of Prolapsed Kidney," by the author, *American Medicine*, December 28, 1901.

diseased and recovery doubtful, more especially as the operation involves no risk, and it is the only positive means of cure.

It must be admitted that a kidney constantly irritated, or in a more or less constant state of congestion when the patient is about on her feet, is a crippled kidney, and that such irritation or congestion, if unrelieved, must lead to inflammation of the organ. It must also be admitted that the constant pressure from belts or corsets, however well-fitted and adjusted, must be a constant source of irritation to a kidney thus crippled.

Upon this subject Henry Morris, in a recent article in the *Lancet*, November 30, 1901, says:

"Belts and bandages have no efficiency in nephroptosis uncomplicated with enteroptosis, and when employed in cases of movable kidney they increase the pain and may otherwise do harm if not carefully and properly adjusted. Though some patients are rendered more or less comfortable by them, they are not cured by these appliances. Moreover, pads and bandages are not free from the risk of doing more harm than good."

According to my own observations, belts are often discarded by patients because of the discomfort they produce and the irritation of the kidney that they are able to observe themselves. Evidence of such irritation is quite apparent upon careful microscopical examination of the urine of these patients if the examination is conducted by an expert, and the specimen selected for examination is taken at the proper time.

	Name	Age.	Married or Single.	Children and Mis.	Diagnosis.	Microscopic Diagnosis.	Microscopical Findings.
1	Mrs. M K	28	M. 2 yrs	1 mis.	Pro. R. Kidney 3d deg. Endometritis.	Oxaluria	Sp. gr. 1028, oxalate of lime, large amount, pus-corpuscles, blood-corpuscles epithelia from pelvis of kidney.
2	Mrs. M S.	[illegible]	M 7 yrs	2 chil 3 mis.	Pro. R. Kidney 3d deg.	Chronic instestitial pyelonephritis with catarrhal cystitis.	Blood-corpuscles (few), pus-corpuscles; epithelia from convoluted tubules of kidney with fat globules. Epithelia from straight collecting tubules of kidney, epithelia from pelvis of kidney with fat globules, epithelia from ureter, epithelia from upper layer of bladder, epithelia from middle layer of bladder with fat globules, free fat globules.
3	Mrs. L M	24	M. 4 yrs	1 child 3 yrs.	Pro. R. Kidney 4th deg. R. hydrosalpinx.	Subacute interstitial pyelonephritis with catarrhal cystitis.	Oxalate of lime, blood-corpuscles, pus-corpuscles, epithelia from convoluted tubules of kidney with fat globules, epithelia from straight collecting tubules of kidney, epithelia from pelvis of kidney with little fat, epithelia from ureter, epithelia from upper layer of bladder, epithelia from middle layer of bladder with few fat globules, few free fat globules.
4	Mrs. A. D.	27	M 2 yrs	3 mis.	Pro. .R. Kidney 3d deg Pregnant 3 months.	Subacute interstitial pyelonephritis with catarrhal cystitis.	Blood-corpuscles, pus-corpuscles, epithelia from convoluted tubules of the kidney with few fat globules, epithelia from the pelvis, of the kidney with fat globules, epithelia from middle layer of bladder with few fat globules, epitheiia from ureter epithelia from upper layer of bladder, mucous, and few free fat globules.
5	Mrs M. G	24	M 7 yrs.	1 child 0 yrs.	Pro. R. Kidney 3d deg. Pro. L. 1st deg. Salpingo-oophoritis, chronic.	Acute interstitial pyelonephritis.	Uric-acid gravel. blood-corpuscles (many), pus-corpuscles, epithelia from convoluted tubules of the kidney, epithelia from pelvis of the kidney, epithelia from ureter, also epithelia from upper layer of bladder.
6	Mrs R	40	M. 18 yrs	4 child	Pro. R. Kidney 3d deg. Pro. L. Kidney 3d deg. Endometritis.	Chronic catarrhal pyelitis and cystitis.	Uric-acid gravel (few), pus-corpuscles, free fat globules, epithelia from pelvis of the kidney with few fat globules, epithelia from ureter, epithelia from upper layer of bladder, epithelia from middle layer of bladder with fat globules.
7	Miss B	20	Single	. .	Pro. R. Kidney 3d deg. Right ovaritis, chronic.	Catarrhal pyelitis.	Incomplete triple phosphates, oxalate of lime, uric acid of three varieties, blood-corpuscles, few pus-corpuscles, epithelia from ureter, epithelia from upper layer of bladder, epithelia from pelvis of the kidney.
8	Mrs. S.	27	M. 4 mos	. . . .	Pro. R. Kidney 3d deg. Pro. L. Kidney 1st deg. Small ovarian cyst of right ovary.	Chronic interstitial pyelonephritis with catarrhal cystitis.	Blood-corpuscles, pus-corpuscles, epithelia from convoluted tubules of the kidney with fat globules, epithelia from straight collecting tubules of kidney, epithelia from pelvis of the kidney with fat globules, epithelia from ureter, epithelia from upper layer of bladder, epithelia from middle layer of bladder with fat globules, free fat globules, mucous, triple phosphates.
9	Miss C.	37	Single	. .	Pro. R. Kidney 3d deg. Anteflection with dysmenorrhœa.	Catarrhal cystitis.	Oxalate of lime, bacteriate (many), mucous, blood-corpuscles, pus-corpuscles, epithelia fromupper layer of bladder, epithelia from middle layer of bladder.
10	Mrs. I. B.	29	14 yrs.	1 child.	Pro. R. Kidney 3d deg. Pro. L. Kidney 2d deg. Retroversion of the uterus.	Chronic interstitial pyelonephritis.	Blood-corpuscles (few), pus-corpuscles, urate of ammonia, oxalate of lime, epithelia from convoluted tubules of the kidney with fat globules, epithelia from pelvis of the kidney with fat globules, epithelia from ureter, epithelia from upper layer of bladder, free fat globules.

My friend, Dr. Gallant, will tell you that he cures these cases of prolapsed kidney with corsets adjusted and worn so as to support the kidney by external pressure upon the abdominal wall. I believe he is sincere in his statement, but believe he is deceiving himself. I have not seen one of his cases that he has cured, it is true, but my experience with prolapse of the kidney convinces me that it is impossible to maintain the prolapsed organ in anything like normal position by any form or artificial support. Hence such support is incapable of curing after the kidney has prolapsed to the third degree or beyond. I am confident that if the urine of these patients be submitted to microscopical examination, there will be found abundant evidence of inflammatory lesion in either the kidney or the pelvis.

The sphere of usefulness of the corset is to prevent or retard an exaggeration of the earlier stages of prolapse (loose or movable kidney), which are inevitably progressive if disregarded. When, however, the kidney has descended below the border of the last rib in front; that is, when its upper pole can be palpated below this point, it is in a position where it is extremely liable to injury and it is constantly subjected to irritation in consequence of interference both with its circulation and the outflow of excreted urine. The most carefully-adjusted support will provoke increased and undesirable and often serious irritation, owing to the pressure it must exert to furnish adequate support.

My contention, then, is, that when the kidney is prolapsed so that its upper pole may be palpated below the border of the last rib in front, it should be fixed without delay, mainly because the organ, one of the most essential to the human economy, is already in a crippled condition, owing to the prolapse, and that we are not justified in delaying operation until demanded either by marked impairment of the health of the patient or by serious disease of the kidney itself. Operation is demanded when the condition is discovered, and if it is done then we will save our patients much suffering and secure better results from the operation.

An analogy is to be found in appendicitis which at one time was considered operable only as a last resort, when there was nothing else to be done, but which now, thanks to the light of modern surgery, has been placed in the list of curable diseases by operation early resorted to. In consequence the mortality has been greatly reduced and thousands of lives are now saved every year which but a few years ago were lost through ignorance and distrust of surgery.

Let us not commit the same error with this condition of the kidney. It is too important an organ to be permitted to remain in a crippled condition when it can be restored to a state of health and usefulness by a simple operation that involves no risk.

Let me enter a strong plea here for more careful and more frequent microscopical investigation of the urine of female patients who we know are extremely liable to the condition under consideration. To be satisfied with testing the urine for sugar and albumin is both unscientific and careless. To regard the detection of albumin necessary for the existence of a nephritis is a serious error, because the amount may be so minute as to make its detection uncertain or practically impossible, or it may be absent, yet grave kidney lesions may exist (Heitzman). It is also a serious error to think the presence of casts in the urine the only microscopic evidence of nephritis (Heitzman).

It is true that some of these women with prolapse of the kidney apparently suffer little inconvenience therefrom, but, without careful microscopic examination of the urine, who can tell what is the condition of the kidney. The great risk is that it may progress to the danger point before it is detected, particularly if the medical adviser happens to be indifferent upon the subject. There can be no excuse for permitting the patient to live thus over a mine which may explode at any time.

2030 Broadway.

The Post-Operative Treatment of Adenoids.—Macleod Yearsley finds that compound syrup of hypophosphites is a valuable medicine to prescribe for children who have been operated on for adenoids, as it contains iron and strychnine, both of which are needed. In children who have been operated upon some time after deafness has appeared, the strychnine will be found of great help to the aural condition. It improves the trophic nerves of the middle ear, and also gives tone to the auditory nerve. As to the hygienic treatment of the patients, good food, good air, surroundings, etc., may be taken for granted. In addition, children should be taught simple breathing exercises, beginning about a fortnight after operation. An erect position, mouth closed, hands together with the arms extended, a slow motion of the arms backward to a little behind the shoulder line while a deep inspiration is taken through the nose. A slight pause and reversal of the process with expiration. This should be done every morning for five minutes, at the normal rate of from fourteen to eighteen respirations per minute. This exercise should be performed in an airy room, or, in summer, in the open air.—*The Medical Times and Hospital Gazette.*

OBSERVATIONS ON GERMAN THERAPEUTICS.

By SIMON BARUCH, M.D.,
NEW YORK.

The sessions of the section on internal medicine of the recent congress of German naturalists and physicians were marked by the rarity of papers on clinical (practical) medicine. Session after session was consumed by the delivery of papers and addresses on bacteriological, chemical, physiological, philosophical—every branch except that paramount one—clinical medicine, to which this section should be chiefly devoted, but which was crowded out by fine-spun theories, philosophic platitudes, and "scientific" papers on subjects much better fitted for the sections on pathology, chemistry, and microscopy. History has repeated itself. Therapeutics, of all branches the most important to the sick and, therefore, to the doctor, has, since the advent of "modern medicine," been treated with stepmotherly regard and scant attention. A retrospective glance over the history of medicine reveals the deplorable fact that the chapters on therapeutics have been the least creditable to our calling. In the earlier periods of medical history, the various schools wasted time and wisdom and much ink in disputation over each other's claims to ascendancy; in these latter days much time and ink and wisdom are devoted to cognate branches, while a deplorable therapeutic nihilism has replaced the former too active medication, and occasional "discoveries" of new remedies, specifics, etc., are thrown "as a sop to Cerberus" in obedience to the demands of suffering humanity, which has cried aloud for relief throughout all these centuries of strife and contention. To the credit of our guild be it said, that although actual curative agents have not been added in noteworthy quantity, much—very much—has been accomplished in the prevention of disease by prophylactic sanitation. In Germany a marked absence of typhoid fever from the morbidity and mortality lists offer a striking illustration of the value of sanitary vigilance. In favorable contrast to our American methods, the supervision of the milk and water supply, which are the chief etiological factors of this disease, is extended to the *source* of supply—the rural districts. As a result, typhoid fever is just now very rare in some parts of Germany. To one who is accustomed to seeing much* of this disease, it was a revelation to discover only two genuine cases in the new Dresden City Hospital (581 beds), and one in the old City Hospital. In the Leipzig Krankenhaus, the presiding genius of which is the well-known clinician Curshman, I saw but one case, in Jena, Halle, and in Leyden's wards at the Charité none; in Goldscheider's wards, at the great Moabit Hospital, only one doubtful case. Such brilliant achievements in preventive medicine entitle German physicians to the highest encomium. Far be it from me, therefore, to depreciate, by the above criticism, the labor of the men who have not only diminished the morbidity statistics of fatal diseases, but whose self-sacrificing labors have given the world a diphtheria antitoxin. My plaint arises from the alarming absence of bedside workers, while every eye is strained, every ambition is spurred, every thought concentrated on laboratory research. It is a sad commentary on the therapeutics of the present time that the main army is occupied, with so-called advance work while only a very small detachment remains as rearguard to cover the retreat and protect the lives of those who are in *present* daily peril from the attacks of the enemy—disease. This was painfully demonstrated by the papers and discussions in the section on internal medicine, about 5 per cent. of which only were of therapeutic value.

---

*On beginning my service in the Hood-Wright Hospital I found three cases, and two days later I saw on West Seventy-second street two cases in consultation, thus aggregating a larger number than those I met in the largest hospitals of Germany (December 1.)

In Leyden's wards, which I had the pleasure of visiting under the personal conduct of the genial professor, the serum treatment of cancer and of chronic rheumatism seemed to engross attention. The chief of the clinic waxed warm in praises of the antirheumatic serum. He showed a case under treatment, but had no recovered cases present. An eminent bacteriologist expressed to the writer serious doubt as to the safety and permanency of this treatment, which he then still had under investigation.

The locations of the great hospitals of Dresden, Halle, and Leipzig deserve passing notice, inasmuch as their environment must contribute vastly to successful treatment. The buildings consist of one, two, or three stories high, are detached, and stand amid parks of trees and grassplots, intersected by well-graded gravel walks. Even in the old Charité and in the great Moabit Hospital of Berlin there are traces of the same tendency, somewhat obliterated now by the great increase of buildings. The Charité is now being entirely reconstructed, the buildings being demolished and replaced successively, so that the service is not materially interfered with. The Moabit Hospital, with Renvers and Goldscheider in charge of the internal division, consists of over a hundred one-story barracks, originally built for cholera cases. Curshman's new pavilions in Leipzig are lofty one-story buildings, on the Eppendorf (Hamburg) plan. They are heated by radiation from the (Terrazo) floor, which contains steam coils within the cement bed. This floor is kept scrupulously clean, and its temperature is under constant observation, on thermometers sunk within a depression in the floor. Curshman pointed with justifiable pride to the lovely park surrounding this pavilion. He orders the beds of all his infectious fever cases to be rolled into the open air and to remain all day.

In the parks surrounding the new Dresden and the Leipzig hospitals large pavilions, open all around, and protected, when necessary, by adjustable curtains, are used for convalescents, who are thus forced to spend most of the time in the open air in contact with that greatest healer—Nature.

It is refreshing to note that while acute diseases are mostly left to their own course, under the best hygienic conditions, there is now very pronounced activity in the management of chronic cases. These opprobia of medicine, which were formerly regarded with disdain in the German hospitals, and are still so regarded in our own country, now receive the lion's share of attention in the best hospitals of Germany. Large halls in the new City Hospital of Dresden and the University Hospital at Leipzig are devoted to Physikalisch-Diätetische Therapie (aptly called Physiologic Therapeutic, by Dr. S. Solis Cohen of Philadelphia, who has edited a work of five volumes on this important subject). The first object that greeted me on entering this hall of the Dresden Hospital was a pale man chopping wood on a large block. My question where the wood was burned, answered with a smile, was that the man was a neurasthenic, for whom this kind of exercise was prescribed by Prof. Windscheid. Presently some twenty men marched into the hall and went through various gymnastic evolutions; others worked the ergostat, turning a weighted wheel, others received various baths and douches, and others practised on the Fraenkel and Goldscheider apparatus for developing muscular coordination in tabetics. One room is devoted entirely to sand baths, which consist of minute pebbles from which the sand has been carefully screened, and which, after being disinfected, is heated to 120 or 150° F. The heating is done in a large kettle, containing a steam coil. From the bottom of this kettle the hot sand issues through a pipe, controlled by a stop cock, into a large wooden tub. When the latter is half filled the patient lies down nude; his entire body, except two-thirds of the chest (to prevent oppression), is now covered with hot sand, a cold, wet turban placed on his head, a blanket over the tub to prevent escape of heat. He now perspires freely, the perspiration trickling through the gravel. Sand is avoided, because it creates much dust, and when applied often forms a cohesive mass which checks heat radiaton. In 1896 I visited the celebrated sand baths at Kœstritz, where the late Dr. Sturm first demonstrated and long maintained the systematic use of sand baths. from which he reported some marvelous results (see "Practical Data on German Health Resorts," *Medical News*, 1896). Professor Curshman dwelt with justifiable pride on this splendid institute for physical therapy, in which his neurasthenics, tabetics, and other chronics are treated with results far exceeding those formerly attained, and warranting the large outlay demanded for the expensive apparatus. The Leipzig and Dresden institutes are on a more elaborate scale, though less ornamental, than that of the best-appointed private sanatoria, many of which I have visited in Germany and France. A novel feature of Curshman's Institute for Hydrotherapy, and one I have only once before met (in Elgersburg), is the Wellen-Bad—wave bath. This consists of a sunken basin, ten feet long, four feet wide, and six feet deep, lined with glazed brick, with the upper end of which another basin, two and one-half feet wide and three feet long, is connected. The latter (separated from the former by a coarse meshed galvanized iron net like that seen around bank desks), contain a paddle wheel of five curved paddles, which revolve rapidly under steam power, throwing strong surf-like waves upon the patient, who stands just outside the iron network partition. This minature surf bath, administered in the large, well-ventilated hall, devoted to hydrotherapy, is said to produce excellent results. Professor Curshman informed me that it increases blood pressure materially, and has been chiefly effective in chlorotic women and neurasthenics. The douche apparatus of this institute, like that in the Dresden hospitals, is imperfect, the supply of hot water not being separate from the main hot water supply, the temperature fluctuates, and is, therefore, unreliable. Moreover, there is no thermometer to indicate exact temperatures; the latter are regulated by a lever, moving from a point marked cold to a point in the middle marked lukewarm, and thence to a point marked hot. This imperfect arrangement for regulating the temperature of the baths I found also in Marienbad and in Professor Brieger's new Hydrotherapeutic Institute of the Berlin University, as well as in the magnificent Kaiser-Bad in Carlsbad. The latter boasts of a thermometer, but it has been broken for some time, without the knowledge of the physician in charge. Not a single douche apparatus in these well-appointed hospitals, nor, for that matter, in any private sanitarium which I have visited, is supplied with a pressure gauge which in our country is now justly regarded as important in the "dosage" of these procedures.

The Leipzig Institute for Physical Therapy is under the special direction of Professor Windscheid, who teaches neurology. When I saw the large and expensively-appointed halls for physical therapy and the large shaded grounds of the Dresden Hospital (63,000 square meters) built and maintained by the city, my thoughts reverted to grim, old Bellevue. The highest flight of imagination could not picture gray Bellevue or Charity Hospital patterned after these models. If ever Bellevue Hospital is demolished (as it certainly should be), and our city authorities construct a hospital worthy of one of the world's greatest cities, the plan of the New Dresden Municipal Hospital (Johannesstadt) would furnish many valuable features. This hospital consists of a series of seventeen separate, handsome, but plain, buildings, which are connected by a well-lighted underground passage of ample breadth and height, on the walls of which are secured the water and sewer and light mains. There are 103 wards and rooms, ranging from one to thirty beds, each now complete and in full operation, and when the buildings are completed the number of beds will be increased to 881. The cost of the land and buildings was $1,500,000; the cost of furnishing, $96,000. The Charité in Berlin is now in process of complete reconstruction. Under the practical and energetic management of Ministerial Director Althof, the old, grimy walls of this renowned clinic are being demolished, and plain but substantial pavilions are rising to take their places. One by one the old buildings succumb to the march of improvement. The surgical clinic, on the side of which stands the statue of Bardeleben, is now approaching completion. Direktor Althof is a remarkable man, possessing marvelous foresight, and displaying marked interest in the development of special practical departments. He it was who developed the enormous advances in hygiene and in the prophylaxis and management of infectious diseases by affording Koch abundant aid and furthering his studies by ministerial backing, without which nothing can be accomplished here. To Althof is due also the construction of the new Institute for Hydrotherapy and Massage and the appointment of a truly scientific teacher for these branches—Professor Brieger. Althof discerned years ago that the Naturärtze (empirics) were making inroads upon legitimate practice. A commission, consisting of well-known teachers, was appointed several years ago to investigate the defects of the existing teaching facilities. Kussmaul, being one of this commission, reported, among other things, as follows: "It cannot be denied that faith in prescriptions is waning among educated people, and that confidence in dietetic remedial methods and in the curative powers of water is in the ascendant. Even the lower strata of society begin to realize how much may be accomplished with air, water, and proper regulation of habits of life without the use of medicine. A distrust against the most powerful and indispensable medicinal agents is becoming more pronounced in large circles. Water is the chief agent, which has won steadily-growing confidence as a remedy, because, unlike others, it may be utilized in varied temperatures and methods, for the most varied therapeutic purposes. According to the correct and skilful selection of the procedure, it regulates the circulation and distribution of blood, the production of heat and tissue change, and influences the respiration and the nervous system. The treatment by water has passed its childhood days, when it not infrequently did as much damage as is done by improper medication. Ripened experience and physiological knowledge have rendered it safe. Hydrotherapy, combined with diet, etc., may undoubtedly bring about, or aid in, the cure of numberless acute and chronic diseases. Of hydrotherapy the young physician knows almost nothing when he leaves the university. Unfortunately, he sooner or later encounters discomfiture when an uneducated quack steps in and cures the patient after he has failed. Deeply chagrined and disappointed in his confidence in scientific therapeutics, he may pass into the camp of the crude empirics. Here lies a great gap in the education of our physicians, here lies the real cause of weakness in the contest for public favor which our physicians must encounter. A revision of our course of study must be made, above all things. The teacher of clinical medicine has already so many duties in his work of instruction that no time is left for familiarizing students with hydrotherapy. In order that the latter may be instructed without the usual superficiality, distinct chairs, supported by clinical divisions, are required, in which appropriate cases may be treated by hydriatic procedures. These lectures may be combined with those on balneology and diet, but, for Heaven's sake (um Gottes Willen), let not this professorship be connected with that on pharmacology."

This energetic report appears to have borne good fruit. In Jena, Professor Matthes is appointed to teach hydrotherapy in connection with clinical medicine; in Leipzig, Professor Windscheid; in Halle, Professor H. Winternitz (not the Viennese Nestor). In Berlin, Professor Brieger was given charge of the new Institute for yHdrotherapy, which he teaches practically and ably, assisted by Drs. Krebs, Lacquer, and Machant. At present clinical lectures are delivered with demonstrations on four days each week, 11 to 12 A.M.

I found quite a number of German, Austrian, Russian, Japanese, and Swiss students in attendance in the large pavilion (constructed for this purpose in the Charité grounds), in which there is an anteroom for policlinic patients, dressing rooms, and a large room for douches, tub, and other baths. In this room Professor Brieger lectures on practical hydrotherapy. In another building Zabludowski teaches massage. Brieger also has another pavilion of thirty beds devoted to clinic (ward) patients, in which physical methods are chiefly applied. In the near future the outfit for hydro therapy is to be greatly enlarged. The appointment of this man of exact science to teach hydrotherapy is fortunate for the development of this special branch of therapeutics. Any one who knows the career of Brieger must feel assured that its merits and failings will be cautiously and methodically studied and taught. Brieger was assistant in the clinic of Quincke at Bern from 1877 to 1878 to Professor Frerichs in Berlin for seven years; in Leyden's clinic, two years. For three years he was director of a separate policlinic in which 2,000 cases of internal diseases were treated annually. For nine years he was chief assistant to Professor Koch in the wards for infectious diseases, containing 115 beds. In 1901 he was appointed professor of general therapeutics with special directions to teach hydrotherapy and other physical methods. In order to obtain a practical insight into this branch of therapeutics, Brieger made a tour of observation of the institutes of Winternitz in Vienna and others. Among his numerous contributions may be mentioned "Contributions to the Knowledge of Fibrous Hepatitis;" "On Chyluria;" "On the Antifebrile Action of the Hydrobenzole Preparations;" "On the Therapeutic Value of Chinolinum Tartaricum;" "Report on 126 Cases of Febris

Recurrens in Professor Frerich's Clinic from July, 1879, to end of 1880;" "On Metallic Heart Sounds;" "On Grouping the Observation of Drugs;" "On Malignant Œdema in Typhoid Fever;" "Clinical Aspect of Tabes Dorsalis;" "On Wandering Pneumonia;" "The Connection of Acute Joint Rheumatism with Nervous Diseases;" "Bacteriological Observations on Puerperal Fever;" "Physiological Action of Purgatives." Those who know Brieger only as the patient and successful bacteriologist, who has given the world an insight into the principles of immunity, of ptomains, toxins, and other intricate laboratory subjects, wonder that he has assumed the care of that orphan child of medicine (hydrotherapy), which, until recently, has received but scant and stepmotherly care in the universities. The man who has a clinical experience of twenty years in the wards of Quincke, Frerichs, Leyden, and Koch, and whose brilliant laboratory work on toxins, ptomains, etc., has proved him a patient toiler in the intricate branches of clinical medicine, will surely bring this neglected child of medicine to full maturity. Minister Althof has again signalized his keen insight into and sympathy with practical medicine by obtaining the consent of this many-sided man to teach a branch of therapeutics which has been hitherto disdained by the great professors. Massage is also taught in a separate institute, under the renowned Zabludowski, in a building on the Louisenstrasse, in which so many university polyclinics are situated.

Physical therapeutics is, therefore, in full swing in Germany; its rise is a benignant "sign of the times;" it will, under the present régime, be developed into the most valuable weapon of the physician, especially against chronic diseases, in which at present he is so powerless. It is a gratifying fact to the writer that in our own country the subject of physiologic therapeutics is receiving much needed attention, a large work of five volumes having recently appeared. It would be well if our medical schools would emulate the German universities and establish special chairs and departments for this branch.

BERLIN, October 15, 1902.

INSTRUCTIONS TO PATIENTS AFFECTED WITH SYPHILIS AND GONORRHŒA.*

By FOLLEN CABOT, M.D.,
NEW YORK.

ATTENDING PHYSICIAN, CITY HOSPITAL; SURGEON TO THE GENITOURINARY AND VENEREAL DEPARTMENT PRESBYTERIAN HOSPITAL DISPENSARY.

IN April, 1898, I read a paper before the Post-Graduate Clinical Society entitled "The Management of Syphilis." The paper was published in the *Post-Graduate* in October of the same year. In that article the following lines appeared: "The patient must understand that syphilis is not necessarily a venereal disease, and he should be told the various ways it can be communicated to the innocent. When instructions of this kind from physicians to patients are conscientiously carried out we may look for a diminution in the ravages of syphilis, and particularly in the innocent. In private practice instructions to patients can be readily given. I believe, however, even in private practice this part of the physician's duty is, in many instances, neglected. It is, however, in dispensary practice that careful instructions to each patient are practically impossible, owing to the lack of time, the insufficient understanding on the patient's part of the few words hardly spoken, and the natural carelessness of many physicians in relation to dispensary work. I believe that a very good way to proceed in dispensaries where syphilis is treated would be to have a small card with printed instructions as to the nature of the disease, etc. One of these cards should be given to each patient suffering from the disease."

Since writing these lines, four and a half years ago, I have been looking for an opportunity to carry out the plan described in the paper. Since my appointment to the Presbyterian Hospital, Genitourinary Outdoor Department, I have had the opportunity of carrying out my previous idea.

The plan has succeeded well, and I present here the instructions in printed form, which are given to the patients affected with syphilis or gonorrhœa.

Instructions to Those Suffering from Syphilis.—Syphilis is a constitutional disease. It is "in the blood." Local remedies and taking medicine for a *few months* will not cure you.

You must be treated for three years.

The effects of this disease are far-reaching, and if treatment is neglected, much trouble and suffering may be caused, not only to yourself, but to others.

The following rules must be observed during the first year:

1. Sexual intercourse should not be indulged in.
2. Alcohol in all forms should be avoided, as it always aggravates the disease.
3. Do not smoke or chew tobacco.
4. Sleep alone.
5. Under no circumstances should any one be allowed to use your toilet articles, as towels, brushes, combs, razors, shaving brushes, etc.
6. No article that has been in your mouth should be used by others, as tooth-brushes, tooth-picks, pencils, pipes, cigars, cigarettes, forks, spoons, drinking-cups, etc.
7. You must not kiss any one, especially children.
8. Brush your teeth night and morning and keep your mouth clean.
9. If you have bad teeth, have them attended to by a dentist, and be sure to tell him that you have syphilis, so that he can take necessary precautions and avoid the possibility of infecting others.
10. Acids in food and drink should be limited.

Instructions to Those Having Gonorrhœa or "Clap."—Gonorrhœa or "clap" is a local contagious disease which requires treatment until the physician pronounces you cured.

To avoid infecting others and to prevent complications, a bubo, stricture, swollen testicles, etc., the following rules should be observed:

1. During the first few weeks walking should be limited. When the discharge is profuse you should keep off your feet as much as possible.
2. Do not use alcohol in any form, as it always prolongs the disease. Drink milk, tea, Vichy, or seltzer, and from six to eight glasses of water during the day.
3. Avoid all sexual relations until you have been pronounced cured by your physician, as the disease may be given to a woman even after the discharge has apparently ceased. When it is present you should avoid sexual excitement, as erections always aggravate the disease.
4. Always wash the hands after handling the parts. The discharge, if carried to the eyes, will cause blindness.
5. Sleep alone, and be sure that no one uses any of your toilet articles, particularly towels and wash cloths.
6. Never lend your syringe to any one, and as soon as you are well destroy it.
7. Be sure that the bowels move every day. If

---

*Read before the Harvard Medical Society, November 22, 1902.

they are inclined to be constipated, take a dose of Rochelle salts before breakfast.

8. Do not use mustard, pepper, horseradish or stimulating sauces on your food.

I believe that all dispensaries and hospitals should adopt some such plan to help educate the public in this matter. We can in this way accomplish much, and gradually, as the public learns of the dangers attending persons who are infected with syphilis or gonorrhœa, we shall have less of these dangerous and often fatal diseases. It seems to me that this is the most rational and practical method of educating an ignorant public. I believe, if such a system becomes general, we shall, in time, have an entering wedge toward controlling venereal disease, and, as a result, also of prostitution.

I sent some of these printed slips to Dr. Morrow, asking him his opinion as to the advantage of such a system. He wrote me as follows: "I highly approve of the slips, which will serve an important educational purpose; and, indeed, recommended them in a paper before the Medical Society some two years since."

In talking to Dr. Lilienthal, and showing him these slips, he said that he considered the plan an excellent one, and that he would suggest its introduction into the Mt. Sinai Hospital.

In getting these cards into their present form, so that they would be understood easily by patients, I am indebted to Dr. McWilliams, Chief of the Surgical Clinic, and to Doctors Kingsbury and Spooner, my assistants, all of the Presbyterian Hospital, for their cordial coöperation.

CONGENITAL ABSENCE OF PECTORAL MUSCLES.

By CHARLES V. BURKE, M.D.,
NEWARK, N. J.

The subject of this record, F. B., aged nineteen years, came into my service at St. Michael's Hospital, out-patient department, to find out what was the matter with his chest.

He first noticed a peculiarity of that part of his body three years previously, and began to take athletic exercises to develop what he thought was weak muscle.

His health is good. He is left-handed; works at the machinist's trade; is pitcher on a baseball nine, using his left arm; boxes and wrestles.

When stripped, the absence of an anterior border to the left axilla is at once apparent to the eye. The examining hand feels the ribs immediately beneath the skin. The axillary artery can be seen and felt pulsating until it disappears beneath the clavicle 3½ inches from the suprasternal notch. The artery can be almost picked up along its whole length.

The sternal portion of the pectoralis major and the entire pectoralis minor are lacking. The clavicular portion of the pectoralis major persists, and is particularly well developed.

The chest shows evidence of rachitis. The ribs are flattened at the sides, more so on the left; and on that side are thrown forward at the costosternal junction, accentuating a sternal depression (funnel chest), extending from the third to the fifth rib.

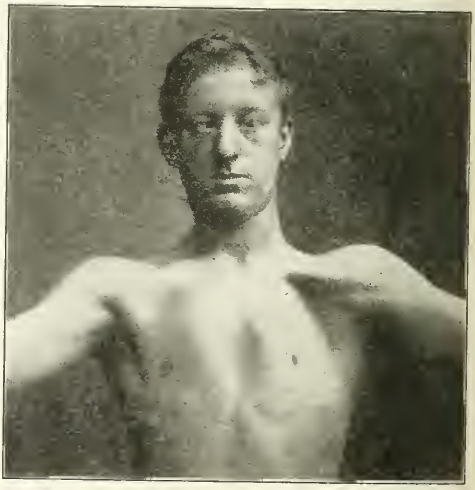
The absence of the pull of the two pectoral muscles on the ribs of the left side must have contributed considerably to this deformity, if indeed it were not alone sufficient without rachitic softening.

The circumference of the chest is 31½ inches in expiration; in inspiration, 35 inches.

The functions of the pectoralis major are chiefly to draw the arm forward and downward, and to rotate it inward upon the chest. If the fixed point is above, the muscle can assist in raising the trunk, and also serve as an auxiliary muscle of respiration.

The chief function of the pectoralis minor is to depress the shoulder by drawing the scapula forward and downward. The salient line visible in the illustration, running from the insertion of the clavicular portion of the pectoralis major to the level of the mamma, is not caused by muscle, but by skin and a small slip of fascia thrown into relief by the elevation of the arm and shoulder. It is, moreover, too far external for the pectoralis minor. When the subject makes the effort that would throw into prominence the pectoralis minor, if it were present (resisted effort to draw the arm and shoulder forward, downward, and inward), this fold does not appear, but the skin is lax, and the hollow is pronounced.

It is of interest to note what perfection of movement the young man enjoys in the absence of this considerable amount of muscle.



I could determine no movement or combination of movements which he was not able to perform with apparently undiminished force.

He pitches a left-hand ball, wrestles, and boxes, and is said to be skilful in all three.

His efforts to develop that side have increased the circumference of the left arm at the insertion of the deltoid ⅜ of an inch above that of the right arm. The measurement of the right arm is 10½ inches; of the left, 10⅞ inches.

There being no evidence of illness, paralysis, or injury, I have accepted the phenomenon as a congenital deformity.

537 Ferry Street.

Collodium after Nose Operations.—K. Pischel advocates the use of collodion in operations on the septum, and turbinals in place of the usual packing. He applies adrenalin to the bleeding surface, and then drops on collodion, compressed air being blown into the nose at the same time, in order to quicken evaporation. Thus secondary hemorrhage is prevented and the wound sealed.—*Archives of Otology.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery

New York, December 20, 1902.

LORENZ'S OPERATION FOR CONGENITAL DISLOCATION OF THE HIP.

THE visit of Professor Lorenz of Vienna to this country, and his cordial reception by the profession of New York and other cities, has centered an amount of public interest in his bloodless operation for reducing congenital dislocations of the hip which is quite remarkable from many points of view.

No greater compliment to his skill in his special line of work could have been given him than has been accorded by the crowds of his fellow workers who have attended his clinics and applauded his demonstrations.

This has been due ,not so much to the fact that the operation itself is of such a complex nature, or so difficult of execution, as the desire on the part of his audiences to witness the detailed and painstaking methods of an enthusiast for a special procedure.

His expertness is the outcome of such large experience that even to such as never expect to treat such cases themselves there has been afforded a very useful object lesson in the perfection of technique which always commands success in any field. The opportunity of seeing master-work in any calling is always inspiring, interesting, useful and suggestive. In such a spirit Professor Lorenz has been welcomed to this country as an honored guest and a distinguished professional brother. No better evidence of the cosmopolitan character of American medicine can be presented than its readiness to learn from any and every scientific man who may have something new to say or something novel to demonstrate.

The method of performing the Lorenz operation is not new, however, to the readers of the MEDICAL RECORD. As long ago as May 29, 1897, soon after Lorenz published his first observations, Dr. Geo. R. Elliott of this city, in an elaborately illustrated article in the MEDICAL RECORD of that date, gave a full description of the procedure, and reported the first American case. This article appeared before Lorenz himself had written fully upon the technique of his operation, and was widely quoted in this and other countries. Since that time the operation has been performed frequently in this country with a due proportion of success.

While the subject is still fresh in the minds of the profession, it may be pardonable to refer also to some of the points in the operation which were presented in an editorial in the MEDICAL RECORD of October 25, 1902, on the occasion of Professor Lorenz's visit to Chicago to treat the little Armour girl.

Although the method was then presented in detail, it will be obviously more interesting in connection with Professor Lorenz's visit to study his manœuvres while he is actually at work, and thus be more directly benefited by the accumulated results of his personal experience. He now seldom uses forcible screw-extension, but relies entirely upon manual force.

The essential part of the operation lies in producing marked flaccidity of the contracted muscles about the joint, so as to get a limb that is practically limp. This is accomplished by using sufficient manual force to overcome all resistance of the contracted muscles. The amount of force required is very great, even to tearing some of the muscles from their points of attachment. The thigh with the leg flexed is forcibly abducted, for it is chiefly the contracted adductors that offer the greatest resistance. An assistant holds the pelvis while this forcible abduction is being made. The attachment of the muscles is forcibly kneaded at the same time. Then the contracted muscles on the posterior side of the joint are stretched. This is accomplished by forcibly flexing upon the trunk the fully extended leg, carrying the foot by gradually intermittent movements quite up to the shoulder.

The patient is now turned upon the stomach, and the anterior muscles of the thigh are forcibly extended by bringing the leg into extreme hyperextension so that the heel touches the buttocks. These various movements are repeated in turn until full flaccidity of the contracted muscles is accomplished. A certain amount of groin skin abrasion occurs.

With the contracted muscles fully overcome so that the leg is quite limp, the second step of the operation, or reposition, is readily accomplished. If the reposition is successful the head of the femur is felt to leap over the posterior edge of the acetabulum with a certain distinct sound.

According to Professor Lorenz, a considerable rigidity of the muscles is still present after reposition, and this is to be completely overcome by repeating the forcible movements before described.

The third and final step in the operation has for its object the formation of a solid acetabulum. By manipulation the soft parts of the acetabular cavity may be molded, but the substantial changes occur when the patient is allowed to go about. In order to retain the head of the bone in contact with the acetabulum, and thus reawaken the process of growth so long dormant, the thigh is flexed at a right angle with the pelvis in a position of hyperabduction so that the knee is posterior to the midplane of the body. The fixation is made with a plaster-of-paris bandage carefully applied about the pelvis, and extending to the knee-joint of the affected side. After a few days the child is urged to walk. Every step tends to drive the head of the bone deeper and deeper into the acetabulum. "Growth is reawakened, the parts are reactivated." Lorenz styles this treatment—the lodging of the head of the bone with the body weight, together with the reposition, as the two chief points in the operation—as decidedly original with him.

Formerly Lorenz removed the first fixation apparatus at the end of three months, and usually subjected the patient to a second fixation period of three months. He now advocates rather longer fixation periods of six months, or even a year or two, according to circumstances.

The particular merits of the operation, as compared with others having the same end in view, is hardly a subject for extended discussion at this time. There is no argument, however, against Professor Lorenz's 60 per cent. of recoveries claimed for a deformity which in times past was considered irremediable. Still operators by the open method—Hoffa's, for instance—claim equally good results. It may yet be a question how much the "bloodless" method surpasses the more surgical ones of treating the parts directly under the eye. In these days of advanced surgery the mere division of tissues by the knife and the immediate instrumental gouging of the acetabulum are no more formidable proceedings than the manipulatory tearing and bruising of subcutaneous parts, and the possible rupture of a large blood vessel. Professor Lorenz is, however, the earnest advocate of the bloodless method —at least in the sense that no blood is seen—and is evidently abundantly able, by his skill and perseverance, to prove its good points.

SOME CLINICAL ASPECTS OF PNEUMONIA.

The season of the year is now with us when respiratory diseases begin to be rife, among which pneumonia takes the first place as the most deadly. It is therefore fitting that current literature on the subject should be widely disseminated and freely read and discussed.

Among papers of note recently published dealing with pneumonia are two of special interest: The first is by the late Dr. Washbourn, and the other by Sir Dyce Duckworth. Dr. Washbourn, late physician to Guy's Hospital and one of the best known of English pathologists, had prepared, before his untimely death, the Croonian lectures, which he had been chosen to deliver for 1902. These lectures had been revised and arranged by some of his colleagues, and were delivered on November 11, by Dr. Hale White. Dr. Washbourn's lectures treat of pneumonia chiefly from a purely scientific standpoint and give an excellent résumé of these aspects of the disease.

However, it is, after all, the clinical features of a malady that most closely concern the general practitioner of medicine, and for a clear presentation of pneumonia, regarded from this point of view, one cannot do better than turn to an article by Sir Dyce Duckworth which appeared in the *British Medical Journal* of November 15. After giving a lucid description of the symptoms of pneumonia and its progress, the English physician proceeds to discuss its treatment. The late Sir William Gull used to say that the essential course to adopt in the case of a patient suffering from pneumonia was to put him in a warm bed, use few drugs, but to be most careful as to nursing. The failure of appetite to be looked upon as only a symptom, and food not to be forced upon the patient. Diet to consist principally of milk and beef tea. With these opinions Sir Dyce Duckworth agrees. So long as the temperature keeps within limits—that is, not higher than 102° or 103°—it is not necessary to take means to check it, but if it reaches hyperpyrexia—105° F.—then steps should be taken to reduce the temperature. Sponging with ice-water and placing a cradle underneath the bed covering will sometimes have this effect, but if not, small buckets of ice may be suspended from the cradle in order to cool the atmosphere. Leiter's tubes, with ice-water over the head or ice-bags placed in the axillæ and on the head, will often give relief. Such remedies failing, resort may be had to quinine in 5 gr. doses every two, three, or four hours until temperature subsides.

The writer does not recommend the placing of the patient in a cold bath, as he considers it a severe and exhausting process and unnecessary. As to internal remedies, the usual procedure of prescribing may be followed: Potassium citrate and ammonia citrate will be found helpful, while quinine is useful in all stages of pneumonia. If the fever continues until the eighth, or even the twelfth, day, there is probably some further disorder or complication; either the patient is in a very low condition and the disease is not resolving properly, or there is some pleural effusion, probably empyema, the presence of which is to be ascertained by the insertion of a needle in the dull area. Delirium through exhaustion is more apt to occur in intemperate subjects and in elderly persons. Pneumonia in the drunkard is always exceedingly serious, while double pneumonia in such subjects is absolutely fatal. Insomnia is the most important nervous symptom, and when occurring toward the crisis is a very grave matter, and opens up the question as to the use of opium. In some cases it is beneficial, but there must be no reason to suppose that the kidneys are affected. Morphine, in small doses, with compound spirits of ether often has an excellently soporific effect.

Failure of heart power, especially in patients after the age of forty, is much to be dreaded and likely to happen. When, through defective circulation, due to the disease, the patient becomes cyanosed, the heart cannot long stand the strain, and if the organ be originally weak it will give way and death will result. This condition may be relieved by bloodletting. If the heart begins to falter and the pulse becomes irregular and small, oxygen should be promptly given, or strychnine may be injected hypodermically, or musk may be used. Stimulants should be given in pneumonia, as in other diseases, when necessary; the younger are generally better without them. If, however, there be engorgement of the side of the heart, high temperature, rapid pulse, the first sound of the heart barely audible at the aortic area, stimulants should be given. In the majority of cases 2 oz. to 4 oz. of brandy are sufficient in the course of the day, but even 12 oz. may be taken with beneficial result. Pure water may be given to the patient *ad libitum*. A mercurial purge may be administered at the onset of the disease, and probably no other aperient will be required throughout the case. In winter time the application of hot poultices to the affected area is a procedure to be recommended. In hot weather these may be replaced by cotton wool, sprinkled with spirits of camphor.

Lastly, Sir Dyce Duckworth says that with a patient suffering from pneumonia there is no need of a steam-laden atmosphere, but the room should be well ventilated.

VACCINATION IN THE UNITED STATES.

On October 28 and 29 the seventeenth annual meeting of State and Provincial Boards of Health was held at Minneapolis. At this conference the question of the production and control of vaccine virus and antitoxin was discussed.

Dr. A. O. B. Wingate of Wisconsin, in view of the fact that vaccine virus of proper strength and of good quality was difficult to procure, urged that some measure should be taken whereby a sufficient amount of protection would be given to the public so as to obtain its confidence. Dr. Wingate thought it would be practicable to have agents appointed to inspect the products of vaccine virus, and, perhaps, the other products, or some means might be adopted by which we could say to the public that these products are safe to use, and that they are efficacious.

Dr. Peter H. Bryce of Toronto, Ont., said that, in his opinion, vaccine virus from a commercial standpoint could be produced quite as well as by a government laboratory. In England no one handles government vaccine except the public vaccinators, who have received a certificate of efficiency from some educational vaccine establishment, of which there are some twenty-five throughout England and Scotland.

He would not encourage the establishment of a national or federal laboratory or institute, where lymphs and serums could be manufactured, until he was perfectly sure the work of vaccination could be put into trained, certified hands, and the work done in such a systematic, routine manner that there would be no question that the lymph will be used this week or next week, when it is fresh. The question was finally referred to a committee, who submitted the following report, which was adopted:

1. That vaccination may be defined as follows: An inoculation by scarification, puncture, or injection beneath the epidermis of a vaccine which produces, with some constitutional disturbance, the typical vaccine vesicle, which leaves, after the pock has healed, its characteristic scar.

2. That, in order to obtain the most satisfactory results, vaccine must be produced either by federal, State or provincial officials, or by private producers under the closest supervision of qualified government officials.

3. That, for the greatest protection against smallpox, State and provincial laws should provide machinery whereby certified public vaccinators must be appointed for the systematic vaccination, by house-to-house visitation, of all children born during any year, and at public stations or otherwise, of such others as circumstances may make necessary.

4. That the evidence of successful vaccination of all school children naturally forms a part of any system of public vaccination, and certificates of such should be accepted only when signed by a municipal or local health officer.

5. That, in order that the best results may be obtained, it is essential that medical colleges should be urged to provide for thorough instruction in the theory and practice of vaccination, and that all licensed physicians must hold certificates of having had practical instruction in the operation of vaccination in medical colleges, dispensaries, or public vaccine stations.

Vaccination as carried on at present in many parts of the United States is unsatisfactory, for the reasons that the vaccine is not always to be depended upon, and that the operation is frequently not performed skilfully and thoroughly. The recommendation that there should be a system of inspection of the virus is to be highly commended. Private manufacturers can produce quite as efficient vaccine as if the making of the substance were put into the hands of government officials, but a rigid system of inspection by recognized competent persons would tend to satisfy the public that an article free from impurities was being used. The recommendation that certificates should be issued to those medical men who have given evidence of being proficient in the technique of vaccination would be another step in the right direction. The opponents of vaccination should be given no just cause to declaim against the operation, nor should they be able in any way to discredit its value in the eyes of the people.

The Dangers of Handshaking.

The pernicious microbe is omnipresent and persuasive beyond belief, and acts upon the minds of certain imaginative individuals with the force of a continual nightmare.

Such persons are obsessed with the idea that hurtful germs are lurking everywhere and are only waiting for the opportunity to pounce upon their unsuspecting victim. To so absurd an extent is this view of the matter carried, that in the most simple actions of every-day life deadly danger to health is seen. Kissing has long been interdicted by these advanced thinkers as an especially dangerous custom, and now it is declared that handshaking is the means of spreading a long string of maladies.

With regard to kissing, there may be some danger in this habit, particularly in promiscuous and excessive salutation of this nature, but handshaking has ever been looked upon as a very innocent and harmless mode of demonstrating one's friendliness, politeness, or respect. The Anglo-Saxon, as a rule, indeed, prefers shaking hands to kissing, and has always firmly put down his foot upon the habit so often followed on the continent of Europe of men using the latter form of greeting when meeting or saying farewell to a male friend. It comes, therefore, as a shock to read that handshaking has been denounced in exceedingly strong terms, and that the advice has been given to discontinue the practice on the ground that disease is thereby spread far and wide.

Dr. J. M. Hirsch of Chicago gives his opinions on the subject in *Popular Mechanics*. He says, in part: "The most delicate perfume upon the hands is neither a sign of freedom from germs, and the most refined are not free from disease of lungs or throat which are rapidly spread by touching the hand that has handled the handkerchief of one afflicted with a cold, catarrh, or consumption. These diseases claim more than one-seventh of all the deaths. Our street-cars carry signs requesting passengers to abstain from spitting therein. These same passengers may hold their hands before their mouths when they cough and cover it with germs enough to infect a thousand people. They may use their handkerchiefs with the same result, and when we have an epidemic of the grip, it is spread by the 'grip of the hand' of a friend or a casual aquaintance or a mere stranger just introduced." The writer then refers to eczema, scarlet fever, and diphtheria, and declares that these diseases are often spread by means of the hands. He also asserts that all germ diseases may be disseminated in this manner.

The above has been quoted merely to show to what extreme lengths faddists will go in order to drive home their theories. As to infectious diseases being spread by the hands, the event in some instances may be possible, but it is always very improbable. Handshaking will doubtless flourish as vigorously as if there were no possible fear of getting into one's system an obnoxious germ during the process.

The Abuse and Control of Hypnotism.

In the October number of the *Contemporary Review* is an article by Drs. F. W. Eldridge-Green and E. G. P. Bonsfield referring to the manner in which hypnotism is being prostituted in Great Britain by adventurers, who by means of specious advertisements take advantage of a credulous public and pervert a useful science to their own sordid ends.

Speaking of the menace to health and morals which may eventuate from the misuse of hypnotism, the writers say: "When a subject is in a hypnotic sleep suggestions may be given that at any time in the future he will perform some given action; the actual time and date may be suggested, or he may be told to perform the action when a certain foreseen probable combination of circumstances occur. Now, in proper hands, post-hypnotic suggestion is of benefit to mankind; as, for instance, for curing deleterious habits. But if beneficial suggestions may be made, so also may detrimental and immoral suggestions, and examples are not wanting in the annals of hypnotism where such suggestions have undoubtedly been made."

The courses published by the self-elected professors of hynotism to induce persons to place themselves in their hands, under the plea that hypnotic influence is not only harmless, but in many instances beneficial to health, are, when not false, misleading.

Therefore, the authors of the paper in the *Contemporary Review* urge that the time has come when the practice of hynotism should be restricted, like that of vivisection, to qualified men, in whose hands it may be used for the good of humanity and not for mischievous objects. Meanwhile the most feasible way of striking at the roots of the matter appears to be the voluntary suppression of the advertisements of these "courses." If the various publishers would refuse to insert such advertisements in their publications, we should, for a time at least, be able to prevent the multiplication of unscrupulous operators.

The advertisements of the hypnotists in England, like those of a similar breed here, are insidious and subtly worded, calculated to make a confiding public believe that nothing but good can come from following the alluring inducements therein set forth, and that the professors of the heralded treatment are actuated by no love of filthy lucre, but are impelled solely by their overpowering love of mankind. A large number of people, avid of something new and willing to be deceived, eagerly swallow the bait, frequently with disastrous consequences. If publishers, both of journals and of magazines, would exercise a wide discrimination, and refuse to insert advertisements of this nature, it would, in the long run, be for the good of all concerned.

Malta Fever.

This fever, contrary to the opinion formerly held, is prevalent in all tropical and sub-tropical countries. It was first observed by English medical officers in Malta and other Mediterranean stations. The condition in some respects simulates typhoid, but differs in other features. Burnett, in 1816, gave a full and clear description of the disease, looking upon it as a remittent malarial fever. In 1878, however, the distinction between Malta fever and remittent malarial fever was drawn. Several cases of Malta fever have occurred in the Philippines which have been described by Strong.

In the report of the Surgeon-General of the United States Army for the fiscal year ending June 30, 1902, Dr. Charles Craig gives an account of the disease. He says: "Various opinions were held by observers as to the etiologic factor in the production of Malta fever, but it was not until the painstaking researches of Bruce were published in 1887 that anything positive was known. Bruce demonstrated the cause of the disease to be a micrococcus, to which he gave the name micrococcus melitensis.

Malta fever is generally a fever of long duration, subject to frequent relapses, presenting a most irregular and confusing temperature course, accompanied with severe pains in the joints, constipation, and profuse perspiration, and often followed by arthritic pains, with or without swelling of the joints. An enlarged and tender spleen is very common. Diagnosis of the disease has heretofore presented many difficulties, as it resembles in many instances typhoid or remittent malarial fever, and even with the help of the microscopical examination of the blood and the Widal test, the distinction between these diseases cannot always be made. In 1897, however, Wright, of the Royal Army Medical School, England, discovered that the blood serum of a patient suffering from Malta fever will agglutinate the micrococcus melitenses in very dilute solution, and that this agglutination test is most delicate and can be depended upon absolutely in diagnosis."

The literature relating to Malta fever among soldiers of the United States Army is very limited. The most valuable report of Malta fever occurring in soldiers of the army is that written by Curry and published in the *Journal of Medical Research*, Vol. 6, No. 1.

Dr. Craig concludes his report as follows: "The important lesson to be learned from a study of the literature of Malta fever occurring in the United States Army is that the conditions are not easily recognized clinically, and may be attributed to typhoid, malaria, or, in the chronic stages, to articular rheumatism. This being so, the great value of a microscopical examination of the blood and the performance of the serum test is at once proven. None of the cases observed by me were diagnosed as Malta fever, and in only one of them was there any suspicion of the occurrence of this disease. Two cases presenting the chronic symptoms would, in all probability, have been transferred to Hot Springs, Ark., for anti-rheumatic treatment, while in two cases presenting the acute symptoms the patient would probably have been treated for either typhoid fever or malaria. In fact, in cases when, on account of finding malarial parasites at different times in the patient's blood, the treatment has been altogether that for malaria, had a diagnosis of Malta fever been made more quickly much discomfort would probably have been saved the patient."

The following conclusions may be drawn from a study of these cases: (1) There occurs in the tropics a fever which may resemble in its acute stage either typhoid or malaria, and in its chronic stage articular rheumatism, caused by the micrococcus melitensis. (2) There is no pathognomonic symptom of Malta fever. The symptoms are so inconstant and confusing that no one of them can be said to be typical of the disease. (3) A differential diagnosis of this fever is almost impossible in the majority of cases without the aid of the microscope and the serum test.

Beriberi and Diet.

In the Medical Record of November 15 the etiology of this disease was made the subject of editorial comment, and Dr. Patrick Manson's views as to its cause were briefly discussed. This authority is of the opinion that the immediate cause of beriberi is a toxin produced by a living germ, and that the toxin does not enter the human body in food. Other medical men who have had experience in tropical diseases—notably Dr. Travers—are of the same mind.

Lieutenant Waterhouse, Assistant Surgeon, U. S. A., reported from Malagi Island, Laguna de Bay, during the past year, concerning beriberi, a part of his report appearing in that of the Surgeon-General of the Army for the year ending June 30, 1902. Lieutenant Waterhouse considers that diet has little to do with the propagation of the malady. He says: "The theory of germ propagation and of infection by personal contact and by place infection appears to me to account more satisfactorily for the spread of the disease. To begin with, we had one hundred prisoners hard at work here for a month and a half without the slightest symptom of the disease; then two cases of beriberi were introduced, and after that the spread was steady. Again, it was noticed that most of the cases came from one set of quarters, the first erected, and that the number of cases from those barracks decreased to a marked degree after scrubbing the bamboo floor with a 4-per-cent. solution of chloride of lime.

"Efficient isolation was impossible, owing to the necessarily limited area of the stockade. Most writers claim that beriberi is due to old, damp buildings, made of stone or of brick, but in this case the conditions were just the reverse, as we had new, airy, spacious barracks, located on high, well-drained ground, with a constant stiff breeze and no flies or mosquitos, conditions apparently ideal for health and the more marked as this epidemic occurred during the dry season, whereas the rainy season is said to be especially favorable to such outbreaks. The fact that the natives go barefooted and that some of the cases appeared in unfloored tents makes one incline strongly to the possibility of place infection occurring from the ground. Another noticeable fact was that of prisoners sleeping next to one another; if one developed beriberi the other was very likely to do the same.

"From the fact that none of the prisoners had developed beriberi prior to its introduction here from a known infected point, of the apparent spread by contact, and of the slight influence which diet appeared to exert over it, the presumption is that we are dealing with a disease of microbic origin, prone to attack those in a run-down and mentally depressed condition, and one which is conveyed by vomits and by close personal contact.

"That it is not very easily contracted unless all the conditions are favorable to its spread is shown by the complete freedom from infection of the entire white population of the island."

The conclusions reached by Lieutenant Waterhouse agree, in the main, with those come to by Dr. Travers, as the result of somewhat protracted and exhaustive experiments regarding the etiology of beriberi. Such testimony, founded upon practical experience, is of the highest value. As yet the mass of evidence goes to show that diet is the most important factor in the causation of beriberi, but, latterly, careful investigation has tended to weaken the idea that it is by any means the sole cause. Further research into the matter will clear up the point, and in the final solution Americans in the Philippines will have the opportunity to play a conspicuous part.

The Dietetic Treatment of Pulmonary Tuberculosis.

Dr. Noel D. Bardswell and Dr. J. E. Chapman read a paper with the above title at the meeting of the Section on Medicine of the British Medical Association on November 1.

The salient features of the paper were as follows: A physiological diet for an average man of 154 pounds, doing moderate muscular work, may be considered to contain 120 grams of proteid, 110 of fat, and 365 of carbohydrate, with a calorie value of 3.008. If this same man were "at rest"—for example, doing clerical work—he would require only 2.500 calories. Such a diet as the following would be sufficient: Proteid, 120; fat, 100; carbohydrate, 240.

The existence of tuberculosis in an individual, however, renders it necessary to considerably change his diet table. The following dicta may be laid down with regard to food, assimilation, etc., of a consumptive: (1) The presence of tuberculosis causes increased waste of all tissues, especially of fat. The indication is, therefore, an increase in all constituents of the physiological diet. (2) The patient may be under normal weight. A sufficient increase in diet, especially as regards fat and carbohydrate, must be made to restore the tissues in addition to meeting the current requirements of the body. (3) Clinical experience and experimental work have shown us that, equivalent for equivalent, proteid has a much greater effect in inducing arrest of tuberculous processes than either fat or carbohydrate. In fact, good results have been so consistently obtained on these high-proteid diets that we now invariably make use of them. (4) Intestinal absorption. The following conclusions are based upon the results of an extended series of experimental investigations: (*a*) The percentage absorption of proteid is normal on moderate diets, and falls somewhat when very large diets are given, but even this is very rarely below 90 per cent. of the total proteid taken. (*b*) The absorption of fats is also normal, and in cases under weight is frequently higher than normal; this absorption remains very high even when very large amounts of fat are taken; for example, a patient taking 231 grams of fat absorbed 96 per cent. In short, our researches have shown us that the consumptive, of whatever clinical type, digests and absorbs at least 90 per cent. of proteid and fat of all food he retains, and the probabilities are that he deals equally well with his carbohydrate. (5) Another factor to be remembered is that patients can be overfed; the good absorption already referred to makes this an easy matter.

In practice, diets are used yielding from 120 to 160 grams of proteid daily for men, with a proportionate reduction for women; with regards to fat and carbohydrates, amounts are given considered necessary to supply the current demands for energy and to restore wasted fat at a moderate pace.

The authors wish particularly to draw attention to their view that, although overfeeding is frequently associated with very satisfactory progress in the lungs, yet the administration of what is practically only a small increase on the physiological diet is quite sufficient to ensure equally satisfactory improvement in the lung condition, with much less risk of injurious consequences, and with the minimum discomfort to the patient.

The practice employed at many German sanatoriums of continually stuffing consumptive patients would not seem to commend itself as the wisest method of treating such persons. Good results, however, are claimed for the excessive feeding process, and while this is the case, the procedure cannot be condemned as wrong. Nevertheless, commonsense characterizes the contention of Drs. Bardswell and Chapman, that if satisfactory progress is made with consumptives when slightly increasing the physiological diet, that it would be absurd to over feed them.

News of the Week

Dr. Keen to Dr. Gallinger.—In an open letter to Senator Gallinger, who, in virtue of a degree granted him by the New York Homœpathic Medical College, in 1869, poses as the medical foe to vivisection, Dr. W. W. Keen of Philadelphia has exposed the folly and ignorance, if not criminality, of the antis in seeking to stifle medical progress by prohibiting all animal experimentation. His text is the successful operation he recently performed on a naval cadet, who was insensible following a football injury, and he affirms that the operation would have been an impossibility were it not for the knowledge of cerebral localization derived from vivisection. He asks Senator Gallinger whether, had the young man been his son, he would have been willing to let him die rather than sacrifice the lives of a few dogs. But antis, like Christian scientists, have no use for logic, and argument is, and ever will be, wasted on them. In his reply the Senator resorts to the quibble that Dr. Keen did not save the young man's life by his operation, since blood clots on the brain have been known to become absorbed. And he also betrays the weakness of his case by accusing Dr. Keen of an attempt at self-advertisement, which, he sententiously remarks, "is prohibited by the ethics of our profession."

The New Jersey State Village for Epileptics.—According to the report of the Board of Managers of Skillman village, the New Jersey State epileptic colony, eighty-five patients have been received at the village since it was opened, in 1898, and of this number nine have been discharged as cured, four have been transferred to other institutions, four have been removed by parents, two have died, and three have run away. During the past year twenty-five male and twenty female patients were admitted, making the total population at the present time seventy-five cases. Dr. Weeks, the medical superintendent, pleads for more buildings for the proper housing and care of the many epileptics now in hospitals for the insane and other institutions in the State. He estimates that there are at least 2,500 epileptics in New Jersey, of whom only an insignificant percentage can be accommodated at Skillman. Concerning the mode of life of the patients, he says that: "as the village progresses, the patients are realizing more and more the advantages of colony life, and are becoming better colonists. More interest has been manifested during the summer and more willingness shown to assist with the work indoors and out, by both men and women, than ever before. The men have been employed at farm work for 9,191 hours, and in grading and caring for the lawns, 3,740 hours. The female patients have been employed at housework, in the laundry, in the sewing room, and during the season many of them were engaged in gathering vegetables from the garden for use in various households and pickling, canning, and preserving berries and fruit."

The Cholera Epidemic in Egypt is declared to be practically at an end. The original outbreak occurred at Moucha, a village some 150 miles south of Cairo, on July 15, and was officially confirmed on the 19th, when 107 cases and 50 deaths were declared. In spite of a military cordon, the disease soon spread, and made its appearance in Cairo in alarming proportions. During the reign of the epidemic nearly 2,000 towns, villages, or hamlets were infected. There were up to the end of November 39,038 cases of cholera, 33,236 of which proved fatal. The epidemic was at its height during seven days, September 9 to 15 inclusive, and during which period there were 9,466 cases, with 8,278 deaths. September 9 was the worst day on record, as the bulletin for the day showed no less than 1,639 cases and 1,371 deaths.

Philadelphia College of Physicians. Section on General Medicine.—At a stated meeting, held December 8, Dr. J. Milton Miller reported a case of arteriosclerosis in a lead worker, aged thirty-two years. The patient, who was presented, had been engaged in the manipulation of white lead for twelve years. He had exhibited a blue line on the gums, but this had disappeared in the course of treatment. The radial arteries were markedly tortuous and resistant, the urine contained albumin and tube-casts, and a systolic murmur was audible in the aortic area. Dr. David L. Edsall presented a patient suffering from typhoid spine. The case occurred in a man about thirty-five years old, the spinal symptoms appearing a few weeks after the termination of the attack of typhoid fever. There was impaired mobility of the vertebral column, attended with pain on attempts at movement, together with irregular elevation of temperature and areas of hyperæsthesia in the distribution of a number of spinal nerves. The condition was believed to be dependent upon perispondylitis. Dr. J. Alison Scott reported a case of typhoid septicæmia with endocarditis. The patient was a man about forty years old, who had presented an irregular temperature-curve, with chills, fever, and sweats, a positive Widal reaction, the presence of typhoid bacilli in the blood as determined by culture, and the signs of an endocarditis resulting in mitral obstruction, but with an absence of intestinal symptoms. Dr. Scott also referred to other cases terminating fatally, in which endocarditis, dependent upon typhoid bacilli, was found post mortem as a complication of typhoid fever. Dr. J. Norman Henry presented a case of endocarditis occurring in the course of typhoid fever. The case had been a most protracted one, and for a time it was thought the systolic murmur audible at the apex was due to relative insufficiency of the mitral valve, but with the recovery of the patient and the persistence of the physical signs the conclusion was reached that there had actually been an endocarditis. Diplococci were isolated from the blood by culture. Dr. James C. Wilson presented a communication entitled "Polyuria in the Course of Enteric Fever." The patient was a physician who, toward the close of his attack, began to pass increasingly large amounts of urine, when suddenly in the fourth week, during defervescence, the amount rose to almost 225 ounces and with equal suddenness declined again to normal limits.

Philadelphia Pediatric Society.—At a stated meeting, held December 9, Dr. Abraham Jacob iof New York delivered, by invitation, an address entitled "Peribronchitis and Interstitial Pneumonia." These conditions, he pointed out, may be primary as well as secondary, not rarely beginning in early life and persisting indefinitely thereafter. They are not rarely mistaken for tuberculosis from the physical signs and the long duration, but, of course, the sputum contains no tubercle-bacilli, and though there is retraction of the chest, with impairment of the percussion note and increased resistance, râles are wanting. There may, however, be roughened breathing, increased vocal resonance, and fremitus, and slight elevation of temperature. The lesions and the physical signs are most commonly situated on the right side superiorly and anteriorly. The treatment, as well as the prophylaxis, is in large part hygienic. Among medicinal agents that are useful are phosphorus and iodine, and, in the absence of fever, iron.

Philadelphia County Medical Society.—At a stated meeting, held December 10, a symposium was held on the "Therapeutic Status of the Coal-Tar Products," papers being read as follows: By Dr. Wahrton Sinkler, "In Neuralgia and Other Painful Conditions;" by Dr. F. Savary Pearce, "In Central Nervous Affections," and by Dr. Milton B. Hartzell, "In the Treatment of Diseases of the Skin." Dr. Hobart A. Hare read a paper entitled "Report of a Fourth Case of Aortic Aneurysm, Treated by Electrolysis." The patient was a comparatively young man, without syphilitic or alcoholic history, in whom an aneurysm of the ascending arch of the aorta developed as a result of injury of the chest-wall, incurred by striking the pommel of a saddle. Twelve feet of gold wire were introduced into the sac and a current of from five to twenty milliamperes was passed through the blood vessel by means of a needle connected with the anode. Temporary relief followed the operation, but bulging appeared in the course of two months in a new situation. The operation was repeated in this situation, but rupture took place in a short while with a fatal termination.

Pathological Society of Philadelphia.—The annual exhibition meeting was held on December 11, and a large number of interesting specimens of most varied kind, together with collections of skiagraphs, were exhibited. Among the more noteworthy were a group of sections of eyes, presenting various abnormal states, by Drs. G. E. de Schweinitz and E. A. Shumway; frozen sections of the head, by Dr. M. H. Cryer; specimens illustrative of various lesions of the brain and spinal cord, by Drs. W. G. Spiller, D. J. McCarthy, C. W. Burr, Chas. K. Mills, and F. Savary Pearce; the bacillus of dysentery, its lesions and antidysenteric serum, by Drs. Simon Flexner and F. P. Gay; lesions of the pancreas, by Dr. R. M. Pearce; lesions of bones, by Dr. John M. Swan; skiagraphs, by Dr. G. E. Pfahler; models of cutaneous lesions, by Drs. W. M. Welch, J. F. Schamberg, and J. M. Wallis.

Hospital Association of Philadelphia.—Twenty-five hospitals in the city of Philadelphia have united to form an association with the following objects: To consider all questions that may pertain to hospital management. To discuss matters and methods that may increase the efficiency of the hospital service. To consider possible abuses and methods to protect hospitals from imposition. To confer when necessary with State and municipal authorities. To devise methods for protection from contagious and infectious diseases. To secure such comity and coöperation as may promote the best interest of all the hospitals of Philadelphia and the public good. The association has been organized for advisory purposes only, and whatever it recommends is to be submitted to the Boards of Managers of the hospitals represented for consideration and action.

A Grave Insinuation against Immigrant Physicians.—At a hearing recently held by the Senate Committee on Immigration on the pending bill to regulate the admission of aliens to this country, Commissioner Williams suggested amendments designed to perfect the administration at Ellis Island, one of which was to punish for perjury physicians who certify to the good health of immigrants who are often afflicted with disease. Dr. A. B. Richardson of the Government Hospital for the Insane urged the passage of legislation to shut out lunatics and insane persons. Mr. Goodwin Brown, representing the New York State Lunacy Commission, proposed an amendment along that line providing for the deportation of any immigrant who shall develop insanity or epilepsy within two years after arrival, on the presumption that that condition resulted from conditions existing prior to landing.

Dispute between a City and a State Board of Health.—About a year ago a boatman at Perth Amboy was found to be suffering from smallpox, and was removed from his boat to the Perth Amboy Emergency Hospital. The State Board of Health requested a physician to take care of the man, and the impression is said to have been that the State Board would pay the expenses of the man's treatment. When a bill for groceries and supplies was presented, however, the State Board refused to pay, claiming that the city of Perth Amboy was responsible. The grocer has sued the State Board for the amount of his bill, and is supported in his contention by the Board of Health of Perth Amboy.

The British Association for the Advancement of Science has, it is said, accepted an invitation from the British South Africa Company to hold its annual meeting in 1905 at Victoria Falls, on the Zambesi River, where a hotel will be erected to accommodate the members. The company has allotted £7,000 for the expenses of the meeting.

The Manhattan Eye and Ear Hospital.—At a recent meeting of the Board of Directors of this institution it was decided to double the capacity of the hospital as soon as sufficient funds could be accumulated to make the desired change. The hospital at the present time has only sixty beds. The new building will contain from 125 to 150 beds, and will be better equipped in every way than the present structure. A man, whose name is withheld for the present, has offered to give $50,000 on condition that $150,000 additional be raised by January 1, 1904, that the hospital be moved to another part of the city, and that a ward for children, which shall perpetuate the name of the donor, be established. It is thought that the new hospital will be erected on east Forty-fourth or Forty-fifth street, between Lexington and First avenues.

A Drastic Anti-Spitting Law.—The City Council of Alton, Ill., has passed an anti-spitting ordinance under which any person spitting on the sidewalks within the confines of the city will be liable to a fine of not less than $5 nor more than $200. The police will be instructed to enforce the ordinance to the letter, and an attempt to keep the streets of Alton clean will be made. The passage of the ordinance is the result of the efforts of many of the women of Alton who made their pleas to health Officer Smith, who, in turn, requested the council to pass the ordinance.

Electric Flash Eye.—Employees of the elevated and other electric roads in the city are said to be subject to visual defects owing to the dazzling flashes of light which shoot from the third rail whenever the connection is broken.

Food Poisoning of Naval Cadets.—One hundred and fifteen cadets in the Naval Academy at Annapolis were poisoned by some sausages eaten at supper one evening recently. The chief symptoms were nausea, colic, and a cutaneous eruption. Many of the cadets were seriously ill, but no deaths occurred.

Plugging Bone Cavities for Caries.—Prof. Mosetig-Moorhof of Vienna, in a recent paper, advanced what he claimed was a new method of treatment of caries of the tibia. He scrapes out the necrotic cavity and fills it with a plug of paraffin and sesame-oil containing iodoform. This, he says, at once arrests the carious process and promotes rapid healing.

Clinic for the Treatment of Trachoma.—The trustees of Bellevue and allied hospitals are preparing to establish a clinic for the treatment of trachoma, which is prevalent among the school children of the city, and for the treatment of which there is at present no city hospital available.

The first floor and part of the second of the old building of the Gouverneur Hospital, which is now in use as a dormitory, have been fitted up for the treatment of these cases. There will be the usual waiting room, operating room, recovery room, and a ward for each of the sexes, in which the patients may be kept for from twelve to twenty-four hours.

The Late Major Walter Reed.—At a stated meeting of the New York Academy of Medicine, held December 3, 1902, the following resolution was unanimously voted:

Whereas, In the recent death of Dr. Walter Reed, Major Surgeon, U. S. A., the science of medicine has lost the one whose brilliant research led first to the demonstration of the transmission of yellow fever by the mosquito and later the practical removal of the disease from a large part of Cuba, and the prevention of its transmission to the shores of this country,

Be it resolved, That the New York Academy of Medicine records its sense of the greatness of the loss to science and to mankind, and its sympathy with the friends and relatives of the deceased.

John H. Huddleston, Secretary.

Obituary Notes.—Dr. Lucy Edwards, sixty years old, was found dead in bed on December 15, at her home in Newark, after having retired in apparently good health. She had locked her room door, and a servant who tried to awaken her in the morning had to summon neighbors, who got into her room through a window and found her dead. Death was attributed to heart disease.

Dr. J. Landis Seitz died of apoplexy at Harrisburg, Pa., on November 28, at the age of forty-five years. He was graduated from Jefferson Medical College in 1882.

Dr. Malcolm Ethan Parrott died at his home in Brooklyn on December 16, aged fifty-six years. He had practised dentistry for several years before his graduation from the Jefferson Medical College in Philadelphia in 1883. He was resident physician and surgeon of the Jefferson Hospital for a short time, and for a year was surgeon of the Red Star Line Steamship Company. He was a member of the Medical Society of the County of Kings, the Associated Physicians of Long Island, and the Brooklyn Medical Society, and was on the staff of the Bushwick Central Hospital.

Dr. Mary Willets, who is said to have been the first woman admitted to the Philadelphia Medical Society, died of cancer on December 17 at the State Insane Hospital in Norristown, Pa., where, for eleven years, she was first assistant physician of the female department. She was gratuated from the Woman's Medical College of Pennsylvania in 1881.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

GENERAL MEDICAL COUNCIL—KING EDWARD'S HOSPITAL FUND—EARL ROBERTS ON CAPTAIN CREAM AND OTHER DOCTORS—GYNECOLOGISTS ON MYOMA AND ADHESIONS OF APPENDIX—COLLEGE OF SURGEONS' MEETING—VIRCHOW MEMORIAL—SLEEPING SICKNESS—OBITUARY.

London, November 28, 1902.

The General Medical Council has been sitting through the week, and has transacted a good deal of formal business, but little of general interest has been done. The president opened the session—the seventy-fifth—on Tuesday, with one of those lengthy addresses which I have more than once called useless. Sir Wm. Turner is a good president, and thoroughly understands the work, but it does seem unnecessary to devote time—which, in this case, is so costly—to telling the members what they know, or ought to know, as well as he does. This time it was the new Midwives' Act which he proceeded to expound, supplemented by remarks on some other things that had occurred since the last meeting.

A vote of thanks being duly proposed, a member declared that thanks were due to the President and Dr. McAlister for being instrumental in getting the penal clause inserted in the act. This led to a curious development. The next day Sir Victor Horsley obtained leave to correct that statement, and claimed the credit of framing the clause for the British Medical Association, by which it was put forward, six years ago. On Thursday a letter appeared in the *Times* from the secretary of the association enforcing that claim. As the new secretary would scarcely know anything about it, he was, of course, put forward by others. Query? If it is wicked of one medical man to write to the newspapers, is the same act of a big association innocent?

Penal cases have occupied the time of the council up to yesterday. One practitioner, convicted of a felony, was struck off the register. Another, found guilty of manslaughter, under unusual circumstances, was not removed. Another, charged with covering, was not proceeded with, as he is now in a lunatic asylum. Another, charged with advertising by means of handbills, was postponed until next session, to give him an opportunity of reconsidering his conduct.

The Prince of Wales presided over a meeting of the General Council of the King's Hospital Fund on Monday. Lord Lister moved the report which recommended the distribution of £100,000, twice the amount available last year. His Royal Highness congratulated the council that they had arrived within measurable distance of the attainment of the King's hope in founding the fund, and that without injuring the Saturday or Sunday funds. He conveyed the King's thanks to those who had devoted their time to this object. Of course, this has been an exceptional year, on account of the coronation gift being handed over by the King to the fund, as well as the other munificent gifts presented in commemoration of that event.

Earl Roberts and Captain Crean, V. C., were the chief guests at the Irish medical graduates' dinner on Wednesday. Sir Philip C. Smyly, president, occupied the chair, and the company numbered about 500. At the request of the president, Lady Aileen Roberts presented the Arnott Memorial Medal to Captain Crean, V.C., who briefly returned thanks, disclaiming any merit. When the war broke out, Dr. Crean was practising at Johannesberg, and joined the Imperial Light Horse; he was wounded at Elandslaagte; served in Ladysmith, and went to Mafeking with the relief force. He acted as surgeon at Tigersloof, continuing his work after being wounded in the arm until another bullet completely disabled him. He was awarded the Victoria Cross.

Professor J. Little, T.C.D., Inspector-General Lloyd, R.N., Colonel Hutchinson, and Surgeon-Captain Bourke, having spoken on previous toasts, Lord Roberts replied to "Our Guests," who said he was proud of his Irish descent, though, unfortunately, he was not born in Ireland. It had been his pleasure to meet many Irish medical men in South Africa, who went out to help the sick and wounded, and he knew what excellent work they did. One member of their association, Sir John Stokes, did not return, and he feared that Sir Wm. MacCormac contracted the seeds of his fatal illness there.

Dr. Herbert Snow brought before the Gynæcological Society a very rare specimen, viz., a "soft œdematous myoma" of Lamson Tait, complicated with three myomata of the ordinary type. Tait found this myoma always solitary; always steadily progressing toward death; accompanied by hemorrhage and painful. All this contrasts strongly with the ordinary multiple myoma. In Dr.

Snow's specimen both forms coexist. There is a round, softish mass as large as a fetal head. When first seen in an out-patient, it was taken for an ovarian cyst, complicated with fibroids, but when the patient was anæsthetized, it was found to be a solid growth—soft, very vascular, embryonic. The finger was easily pushed into the pulpy tissue. At each corner of the fundus, a hard, tough myoma of the size of an orange, sessile and interstitial, and behind one of them another, smaller, with a thin pedicle, form the complications. The microscope shows the myoma to consist of unstriped muscular fibers, with large nuclei and numerous leucocytes—in fact, to be much more embryonic in structure than ordinary myoma, and apparently passing into myosarcoma.

There were no adhesions, but great vascularity of the tissues. The mass was dissected out from the cervix by a flap operation, and the flaps sutured. The abdominal was closed in two layers, after saline fluid was poured into the cavity. Recovery uninterrupted.

Mr. Mayo Robson (chairman) commented on the rarity of the case. He thought he had met the combination, but in the absence of his notes, he could not assert that he had.

Mr. Bowerman Jessett had seen one or two cases in which a soft myoma inside the uterus was present, with other fibroids outside.

Dr. MacNaughton Jones said the specimen had the appearance of a large fibrous tumor enclosed in a capsule, and suggested that degeneration might account for differences in consistency.

Some interesting cases, involving the appendix vermiformis, were mentioned at the Gynæcological Society, apropos of specimens shown by Dr. Macnaughton Jones of (*a*) an adnexal tumor with the appendix; (*b*) a large blood cyst of the right ovary, with left cystic ovary and hydrosalpinx. As to the first, Mr. C. Ryall said he was present at the operation, and the way the appendix was attached, not only to the Fallopian tube, but to the ovary and surrounding parts, was remarkable. He also mentioned a case of double pyosalpinx, on which he had just operated, in which he diagnosed implication of the appendix, and found it distended at its extremity beyond a stricture and adherent. The other tube being affected, both were removed. Mr. Jessett mentioned several cases of adnexal trouble involving the appendix; in one it was attached to the stump of an old operation; he agreed with Dr. Jones that it was well to examine the appendix in all operations for adnexal troubles. Mr. Mayo Robson had had at least three such cases. Lately he removed the appendix attached to the stump of a uterus removed twenty years ago by an eminent operator. In all cases with pain in the right ovary unaccounted for by prolapse, with tenderness between the anterior spine and the umbilicus, he examined the appendix, and that was one reason against vaginal operation for adnexal disease.

Discussion as to another point in adnexal disease took place at the same meeting on a paper by Dr. Mcnaughton Jones. The point was the propriety of conservative procedures in cœliotomy for such cases. Should both ovaries be removed when there was only cystic disease in the second? To this Dr. Jones said no—but when there was doubt as to the prudence of a conservative procedure, and the probability of a future operation being necessitated, it was different. Nothing could justify the removal of sound adnexa, but if they were so diseased as to render the success of an attempt to save them improbable, they should be removed.

Mr. Furneaux Jordon's experience was that conservative operations on one side had little chance of success when the other was incurably diseased, and it was rare to meet lesions warranting removal on one side with no disease on the other. He thought patients were less anxious than their surgeons to save their appendages.

Mr. Mansell Moullin said the age of the patient should have some influence in doubtful cases. If over forty, he would remove them, but in a young woman, he would try to save them.

Dr. Edge said a fairly healthy ovary need not be removed, even if the tube on that side must.

Mr. O'Callaghan quoted Lawson Tait's dictum that if the appendages were not removed on both sides in such cases, a second operation was always required.

Mr. May Robson thought that Tait only referred to gonorrhœal cases in that statement. For himself, Mr. Robson questioned if it was ever right to remove a healthy ovary because the other was diseased.

The annual farce of the Royal College of Surgeons was enacted last week. For the nineteenth time the members and fellows were permitted by the council to meet in their own building, and offer certain resolutions which, of course, were negatived. Some questions were put to the president asking explanations about the report of the last meeting. As to one, the president said it was legally and ethically right for the council of the college to choose the representative in the General Medical Council. Thus the twenty-four councillors hold fast to the right, as they declare it, to choose one of themselves, and, moreover, to prevent the 16,000 members of the body corporate being consulted. If right and legal, of course it is ethical. The legality is only based on the assumption. At first it was proposed to contest the point in the courts, but the money was not forthcoming. The council pretends that it represents the members as well as the fellows—a very foolish pretense, considering that no member has any vote in the election of the council, or on any other matter.

We are taking a share in the memorial to Virchow. Lord Lister presided at the inaugural meeting, and about one hundred well-known men have joined the committee. Lord Avebury is treasurer of the fund, which will go toward the statue to be raised in Berlin.

The monument to Virchow will, therefore, have an international character, and other nations will, no doubt, contribute.

The Commission sent to Uganda by the Royal Society and the Foreign Office to investigate sleeping sickness has apparently made fair progress, for Dr. Low, the pathologist, is reported to be on the way back, having finished his part of the work. Dr. Castellani, the bacteriologist of the commission, is continuing his research in the country, and the third member, Dr. Christy, will continue his studies along the Upper Nile, by which route he will return It is reported that the cause of the disease is bacterial, and not filarial, but, of course, nothing authoritative can be stated until the commissioner has returned and reported.

Among recent deaths announced are several old members of the profession—three octogenarians, viz., Dr. Chubb of Torpoint, aged eighty-two years; E. D. Hacon, F.R.C.S., aged eighty-four years, and Dr. Oldham, F.R.C.P. aged eighty-eight years.

OUR PARIS LETTER.

(From Our Special Correspondent.)

OPERATION FOR HYPERTROPHY OF THE PROSTATE—CURIOUS INCIDENT AT THE SOCIETY OF BIOLOGY—CONGRESS OF SURGERY—NARCOSIS—SUPPURATION OF THE PANCREAS—GASTROENTEROSTOMY AND ITS TECHNIQUE—FEMALE ELEMENT IN BERNE UNIVERSITY.

Paris, November 28, 1902.

At a recent meeting of the Society of Surgery, the question of operation for hypertrophy of the prostate came up for discussion. Of the younger school of surgery, Dr. Leguen and Dr. Albarran are those who favor it the most. Dr. Leguen, who has now been surgeon of the hospitals for about five years, described the results he had obtained in twelve different cases in which he performed prostatectomy. One patient died, an old man of seventy-two years, who showed symptoms of infection and whose kidneys were diseased. Speaking of the technique followed, Dr. Leguen said he considered it well to incise the urethra as soon as possible, as it was generally cut later on in the operation, and with doubtful results. The whole gland should be removed, and not piecemeal, but in large sections. Complications, such as hemorrhage and tearing of the rectum in two instances, had been observed, but with no subsequent fistula. Incontinence of urine was seen after two operations, but experience had shown him that this was likely to be only temporary. Indications for the operation are specially to be found in the very considerable size of the prostate, and this, with dysuria, followed by retention, would justify an operation. Calculi are also a good indication, and may be removed by the same operation.

Dr. Albarran is a Cuban, who was naturalized and became Dr. Guyon's favored pupil. He married Dr. Guyon's daughter, and in good time was named surgeon of the hospitals. He still has a foreign accent when speaking French. Dr. Albarran and Dr. Bazy have several times had discussions at the Society of Surgery as to the advisability of catheterizing the ureter, Dr. Bazy considering it well to employ this exploratory method in certain well-determined cases, and not using it as frequently as Dr. Albarran does. He has performed prostatectomy forty-two times, and has lost but one patient from cachexia. The latter was seventy years old, and had pyelonephritis on both sides. Dr. Albarran felt he could not, as yet, discuss the indications of this operation, which had not as yet been performed a sufficient number of times.

The Society of Biology, the finances of which were not, it seems, in a very flourishing condition, has just received a gift of 10,000 francs, which were delivered anonymously in a sealed letter to the president of the society.

At the Congress of Surgery, which was held in Paris last October, the time-honored question of narcosis came up again for discussion without anything definite being decided. There is no doubt that ether is slowly but surely superseding chloroform among members of the younger school, and even the A.C.E. mixture is mentioned. Dr. Julliard of Geneva said he had operated in 9,289 cases in which narcosis was obtained by the use of ether, and he had so far not had a single death. Asphyxia supervened in three cases, and was cured by artificial respiration. Bronchial pneumonia was largely due to the fact that the patients were insufficiently protected, or that the mucus which accumulated was not removed with sufficient care. Roux of Lausanne has a distinct preference for ether. The A.C.E. has already been tried in Vienna, as well as in England and Italy, and Dr. Reynès of Marseilles has found it of advantage when operating on weak and old patients, or when there are cardiorenal or bronchopulmonary disorders. Chloride of ethyl is also being used more and more, and the least amount to be given is five cubic centimeters every five minutes. The period of anæsthesia is followed by one of analgesia which lasts sometimes just as long. When the operation is to last more than half an hour, it is well to use this preparation and then chloroform or ether.

Suppuration of the pancreas has been recently observed by Dr. J. L. Faure of the Paris hospitals, and he described the two cases he had seen. A young woman was taken ill with symptoms of perforation of the stomach, and, on being operated, was found to have a large collection of pus back of the stomach. Gangrene of the pancreas had set in, and the fistula, which remained a long time after the operation, showed that the pancreas was the primary seat of the disorder. In the second case the patient, who had lost fifty kilos in weight, was supposed to have cancer of the stomach. Instead of this, a large mass of adhesions was found, and the latter were due, undoubtedly, to previous suppuration of the pancreas. The patient made a good recovery.

At this same Congress of Surgery the different techniques employed in gastroenterostomy were discussed. Monprofit of Angers has performed gastroenterostomy 707 times. Woelfler's method of anterior anastomosis he only employed fifteen times, whereas von Hacker's was used seventy-five times and Roux's Y-method thirteen times. The latter would be the best, but takes more time, and can only be used when the patients are sufficiently strong to stand an operation of an hour's duration. Dr. Hartmann spoke of the sixty operations he had performed for non-cancerous lesions of the stomach, and for which he had only a mortality of 16.5 per cent. to declare. Since 1900, out of thirty-seven cases, there have only been four deaths, which is only a mortality of 10.5 per cent. Dr. Hartmann complained of the patients' being sent to him when they were already weak and emaciated, though an exception should be made for the patients sent by Dr. Hayem and Dr. Loupault, who have made a special study of stomach troubles. An accurate diagnosis should always be made, as he does not consider it well to operate on all forms of chronic dyspepsia. As for his technique, it is that of von Hacker, which has never been followed by the complication feared by Roux—the circulus viciosus. Dr. Roux of Lausanne said he did not consider that gastroenterostomy was sufficient in ulceration of the stomach, as cancer may come on afterward. Excision of the ulceration should be carried out in such cases, and, as for profuse hemorrhage, he considers it well to operate immediately under such conditions. Dr. Pauchet of Amiens has performed thirty-three operations for non-cancerous disease of the stomach, and he only reports two deaths. According to his views on the subject, the symptoms command an operation much more than the diagnosis; for instance, vomiting, hemorrhage, pain, loss of flesh, and mechanical changes of the stomach. When the patient is in good condition, Roux's method is undoubtedly the most favorable.

Since the promulgation of the recent laws, which prevent foreigners from obtaining the State diploma of medicine unless they pass the preliminary examinations required of French students, a certain number of Russian students have gone to Swiss universities. At Berne, for instance, there are almost as many foreign students as native students. In the medical department there are 252 women students to 199 men students.

SYPHILIS IN THE BARBER SHOP.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: Dr. Antonio Fanoni (page 936 of your issue of December 13) and other readers of the MEDICAL RECORD will be interested in the following quotation from I. K. Proksch, the most eminent historian of syphilis ("The Need of the Study of the History of Medicine," 1901, page 7):

"From the end of the fifteenth century down to the present time the literature is overfull of the reports of the communication of syphilis from secondary affections of the mouth by drinking cups, kissing, biting, licking, nurses, nurslings, etc. As early as 1496 the medical men (or rather, and literally, the barbers) were forbidden, under a fine of ten guldens, ever to employ again such surgical tools as had been used on syphilitic persons (Ch. G. Gruner *de Morbo Gallico Scriptores*, Ienæ, 1793). What amount of misery must have occurred before that order became necessary! Nevertheless, an epidemic of syphilis originated in Brünn, in 1577, from a barber shop, by the use of cupping instruments. Its history was reported by Thomas Iordanus (*Luis novæ in Moravia Exortæ descriptio*, *Francofurti*, 1580) and Ioannes Sporischius (*Idea medici*, *Francofurti*, 1582). Several other extensive infections, caused by cupping instruments, occurred in Germany and were reported. In the year 1805 I. N. Rust (*Helkologie*, Berlin, 1811) made the discovery that a large number of the Hebrew infants in Cracow became syphilitic from the lips of the circumcisors. . . . During the last four centuries more than a thousand monographs have been written on the extragenital contagion of syphilis."

A. JACOBI, M.D.

The Boston Medical and Surgical Journal, Dec. 11, 1902.

Leucoplakia.—Frederick C. Cobb, discussing the etiology of this affection, says that of all irritants tobacco is, perhaps, the most effective. Leucoplakia has been called "smoker's paralysis." As to treatment, the evidence is most conflicting. Cases treated by papayotin, by excision, by cautery, and by "let alone," are all credited with successful results. On the other hand, many leucoplakias, in spite of all treatment, end in carcinoma. Butlin recommends soothing alkaline lotions and ointments, with avoidance of the cautery and all irritants, and decrease or abstention from smoking. If the patch, in spite of all these measures, remains stationary, and, above all, if induration or warty growth or any appearance of cancer suggests itself, thorough excision of the patch is advised. Of ten cases occurring in the Massachusetts General Hospital four developed carcinoma.

Infantile Paralysis; an Epidemic of Thirty-eight Cases.—Charles F. Painter reports these cases, which occurred in the summer of 1900 in Gloucester, Mass., within a radius of four miles, and which go to show the possible infective and epidemic character of this disease. The author thinks it probable that there may be several organisms capable of producing this symptom complex, given the proper conditions present in the individual; and that of all the contributive factors which prepare the way for the entrance of a bacterium or a coccus to the anterior horns of the cord, perhaps the one most to be reckoned with is the exposure to temperature changes through the vasomotor system; it is to be noted that the majority of cases occurred on, or more frequently twenty-four to thirty-six hours after, periods of extreme heat, and in some cases after a sudden or sharp drop from an abnormally high temperature; in other cases they followed bathing in the ocean. There were twenty-three males and nine females. The youngest was thirteeen months and the oldest ten years. Twenty-one cases were three years or younger; eight cases two years or younger, and seven cases four years or older. No cases observed got entirely well, and only one died, though this one was not included among the thirty-eight reported.

Journal of the American Medical Association, Dec. 13, 1902.

Alcoholic Epilepsy.—T. D. Crothers considers the convulsive and maniacal types of the malady, those cases attended with dementia and confusional states and, finally, psychic cases and those attended with automatic trance. Illustrative clinical histories are given under each of these headings. He offers the following conclusions: (1) Alcoholic epilepsy is increasing rapidly in this country. (2) It is a psychosis and neurosis which should be recognized, having distinct symptoms, the recognition of which is imperative in the treatment. (3) Where the toxic symptoms are convulsive and explosive and come on suddenly, the future of the case is very ominous and the warnings from these symptoms should be heeded. (4) The connection between mixed drinks and these spasmodic symptoms are traceable, and should be considered in the prognosis and treatment. (5) The treatment and curability of these cases can be carried on with great hopefulness, and undoubtedly in the future will become a prominent part of the work.

The Pathology of Chromidrosis.—M. L. Heidingsfeld maintains that this malady is not as its name would seem to imply, an anomaly of secretion. Judging from the limited number of cases in the literature, and as a matter of common observation, it is an exceedingly rare affection as regards forms characterized by yellow and brown and probably black, blue, green and intermediate shades of discoloration. Red chromidrosis is an entirely different and by no means an infrequent type of affection, with an extraneous cause, probably some form of erythro-micrococcus-tetragenus infection from individual to individual and yielding to antiparasitic remedies. In the light of this investigation the pigmented elimination, in the yellowish-brown forms at least, is insoluble in water, alcohol, ether, etc., is readily soluble in chloroform, stains linen indelibly, shows no reaction when treated with ordinary reagents, and is amorphous, homogeneous and resinous in character. Pathologic examination reveals the sudoriferous glands of the affected area to be normal, sebaceous glands absent, a hyperkeratosis around the openings of hair follicles, and pigment accumulations near the hair follicles, in the stratum corneum, lower layers of the rete, and the adjacent cutis. The pigment is grouped in cell-like masses, is not finely granular, and does not bleach with hydrogen dioxide like chromophores. Spectroscopic examination of the eliminated pigment reveals no absorption bands, and hence it is not a derivative of oxyhæmoglobin. In view of the pathologic findings, the absence of sebaceous glands, the normal condition of the sudoriferous glands, cases of so-called chromidrosis (excluding red forms) are anomalies of pigmentation and not glandular secretion.

Medical News, December 13, 1902.

Remarks on One of the Complications of Anæsthesia (Asphyxia).—Thos. L. Bennet does not use the word asphyxia here in its literal sense alone, of death through the respiration, but rather denoting the condition produced by a lessened percentage of oxygen, or an increased percentage of carbon dioxide, or both, in the blood. This state is produced in a number of ways during the administration of anæsthetics: (1) By the simple exclusion of oxygen, as in the inhalation of pure nitrous oxide, or highly concentrated ether vapor. (2) By paralysis of the respiratory center from over-narcosis, producing failure of the respiration. (3) By the production of a condition, the exact nature of which is unknown to the writer, a condition in which cyanosis is marked notwithstanding free respiration, and no exclusion of oxygen. This most frequently complicates the administration of chloroform, and is usually associated with some circulatory depression. Close observation has led the writer to believe that it is due either to a paralyzing effect of the anæsthetic upon the blood-corpuscles, suspending their function of carrying oxygen and carbon dioxide, or to failure of the pulmonic circulation, this, in turn, being due to depression of the cardiac and vasomotor mechanism, or to paralysis of the walls the pulmonic vessels, resulting in such inefficiency of the lesser circulation that proper aeration of the blood is not accomplished. (4) Asphyxia complicating anæsthesia is most often produced by mechanical obstruction to respiration, resulting from (*a*) narrowing of the air passages from within, *e. g.* from tuberculosis, carcinoma, etc.; (*b*) narrowing of the air passages from without, from pressure; (*c*) other forms of pressure upon the respiratory organ, *e. g.* tympanites; (*d*) diseases of the lung limiting respiratory capacity; (*e*) certain positions required in the operation; (*f*) certain operative manipulations which interfere with respiration by distortion, etc.; (*g*) foreign bodies in the air passages; (*h*) stertor and stridor; (*i*) a short, thick neck, or a long, thin nose may act as an obstruction. The treatment of asphyxia under these circumstances is the least part of the subject. The patient must not suffer from deprivation of oxygen, or breathe an excess of carbon dioxide, or have his respiration obstructed. An open airway should be maintained. Anæsthesia by nitrous oxide alone or mixed with air or with oxygen is the form of anæsthesia most often complicated by asphyxia. This is the chief risk of the administration, and patients who should not be exposed to this risk should have some other anæsthetic. Whenever a certain degree of asphyxia necessarily complicates anæsthesia, it may be relieved by the administration of oxygen throughout the narcosis. Excessive asphyxia calls for such measures as pulling forward the tongue, artificial respiration, intubation or tracheotomy. The last should not be too long delayed.

New York Medical Journal, December 13, 1902.

The Present Status of Genitourinary Therapeutics.—Eugene Fuller refers to the following point: the elimination of the gonococcus, the dissipation of general infection from the genitourinary tract, the sterilization of the tract in connection with operation, and the limitation in the use of anodynes. In reference to the gonococcus, he says that if the germ is simply washed from one place to another, more harm than good is done. We should rather make a topical application to the exact site of infection. For the elimination of general infection we must rely on diuresis, the administration of drugs by the mouth to inhibit germ proliferation in the urine, on vesical and urethral, lavage, and attention to the general condition. Concerning sterilization previous to operation, the author says that this term has merely a relative significance, as absolute sterilization is quite impossible For instance, he would not anæsthetize his patient and spend fifteen minutes in washing out the bladder before beginning operation. He would prefer to operate at once, and thus lessen the time the patient would be under the anæsthetic. Finally, he objects to the use of opium and its derivatives just before operation. They check diuresis and thus thwart nature. Consequently if a patient comes to the operation table narcotized there is the added risk of a fatal result from uræmia or sepsis or a combination of the two. He is always alarmed if after an operation the patient is comfortable and drowsy, for he fears uræmia. In non-operative conditions, of course, anodynes may find their proper field.

The Treatment of Extensive Rectal Strictures.—E Ries suggests an operation designed to replace those end-to-end anastomosis after resection of the diseased portion of the bowel and side-to-side anastomosis without resection. In the case narrated by him the following condition was found: Vulva patulous; the perineum consisted of an upper part composed of skin only and a lower portion containing part of the sphincter, the two portions being separated by an opening leading into the vagina, a vulvovaginal fistula. The posterior wall of the urethra was torn away from the anterior wall to the extent of about one inch, and the orifice of the remnant of urethra was so narrow that an ordinary catheter could not be inserted—stricture of the urethra. The posterior column of folds of the vagina was torn away from the perineum. Immediately below the end of the column of folds a narrow fistula led into the rectum and discharged (during the examination) liquid fecal matter. A finger introduced into the rectum about two centimeters was arrested by a callous stricture, which would about have admitted a match. The portion of the rectum immediately above the stricture was felt through the vagina as a hard string, extending upward for more than five centimeters. The vagina was wide, the uterus small and atrophic. Bimanual palpation of the pelvic organs revealed, as an additional and somewhat puzzling finding, high up on the brim of the pelvis, a hard, immovable mass around the rectum, which was assumed to be an exudate around the rectum caused by ulcerations. Operation revealed the fact that the sigmoid portion of the bowel could not be pulled down, and that it contained a second stricture higher up. The plan of operation was thereupon changed, and the following method followed: A median abdominal incision about 10 cm. long revealed in the sigmoid the stricture intimately adherent to the pelvic wall, its mesentery so shrunken that this portion of the gut was immovable. Above it the bowel was somewhat distended and remarkably freely movable as high up as could be felt. It was provided with well-formed mesentery with numerous vessels. About 3 cm. above the upper end of the stricture of the sigmoid, in a healthy portion of bowel with healthy mesentery, the bowel was cut in two, the assistants providing against the escape of fecal matter from the cut ends. The incision was continued through the mesentery, and the bleeding vessels of the mesentery were ligated. The strictured portion of the bowel was closed above with three layers of continuous, inverting catgut sutures. A long artery forceps introduced through the vagina and the opening in the cul-de-sac took hold of the healthy colon and pulled it down toward the anus. There was hardly any tension of the bowel, so that it could be expected that stitches would hold the colon down until it had become firmly adherent. The abdomen was closed with silkworm sutures and the operation was completed through the vagina. On the return of the patient into the lithotomy position, the lower end of the healthy bowel was found very close to the anus, and the entire length of the healthy gut fitting snugly into the opening in the cul-de-sac and the incision of the anterior rectal wall, so that the peritoneum was not closed by any suture, but reliance was placed on the bowel and its mesentery to prevent leakage into the peritoneal cavity. The rectum and sigmoid were washed out and iodoform gauze was inserted The descended end of the gut was fastened to the rectum below the lower end of the rectal stricture by four silkworm sutures. The vaginal edges of the rectovaginal fistula were cut away, and thus the entire incision in the vagina formed one straight line from the cervix to the anus. It was closed with silkworm sutures, and the sphincter united by similar sutures after a rubber tube had been inserted into the colon. The patient made a good recovery.

American Medicine, December 13, 1902.

Accessory Thyroid Tumor Situated at the Base of the Tongue.—Randolph Winslow reports this case. His patient was a girl of seventeen years, who had always had some trouble with her throat. The voice was muffled and indistinct, and swallowing was difficult. An ovoid mass extended well across the base of the tongue, just in front of and completely hiding the epiglottis. It was smooth and covered with red mucous membrane. The opening of the larynx could not be seen. The growth was about half the size of a hen's egg, and felt somewhat elastic to the finger. It was not painful. The growth was removed through an incision made from the chin to the hyoid bone. There was some bleeding, but it was not alarming, and the whole wound healed by first intention.

Infantile Diabetes Mellitus.—Myron E. Fisher reports the case of a child of twenty months, who was in convulsions when he was called to her. The axillary temperature was 105.5°. A warm pack controlled the convulsions, and later the temperature was reduced by wrapping the child in sheets wrung out of cold water. Three or four days later the mouth was found drawn to the left side, and it was found that there was a right hemiplegia. During the first year the use of the leg was restored, but the arm improved very little. A little more than two years after the attack the child began to pass large quantities of urine, was very thirsty, had a voracious appetite, and was feverish and irritable. The twenty-four-hour amount of urine was two quarts. It was very pale, almost odorless, with a trace of albumin, and a very large quantity of sugar. An unfavorable prognosis was given. Starches and sugars were eliminated from the diet, but the child began to decline rapidly. She had attacks of dyspnœa, and lost flesh. She finally relapsed into a comatose state and died.

Some Neglected Points in the Physiology of Vision.—George M. Gould declares that the observation underlying all theories is that the persistent action of the light-stimulus or image upon one part of the retina quickly lessens and extinguishes the sensation-response. The reinstatement of sensitiveness is by means of shadings, darkness, and variations of the stimulus. The writer then goes on to enumerate the devices and methods whereby this deterioration of function is prevented: (1) The shadows cast by the retinal arteries, veins, and capillaries, according to the direction and intensity of the entering light, are constantly shifted and modified, so that the retina behind them and in their immediate neighborhood is allowed variations of fatigue and recuperation. The most shaded portions serve, perhaps, as centers, whence extends the mysterious resensitizing process. (2) Certain sensitive and strained eyes, when looking toward the sky or a bank of cloud, can see a multitude of little flashing lights. These may resolve into illuminated paths or lines of light. These have been called phosphenes, corpuscular reflections, phoses, and aphoses. They are the reflections from the blood-corpuscles of the capillaries of the retina, which act as tiny mirrors. These corpuscles cast unobserved shadows upon the retina. The reflections may also have a function in producing needed physiologic irritation in parts of the retina not habitually stimulated by the incoming light, and in this way keeping it in a state of preparedness or responsiveness. (3) The shadows of muscæ volitantes are probably of greater service. They should be regarded as of physiologic, not pathologic, significance. They exist in all eyes, although not usually recognized. Every part of the fundus of all eyes during the waking life is protected by the muscæ shadows. (4) The retinal pigment extends so far toward the retinal periphery that functionally it joins that of the iris in preventing all light, except the little possibly transmitted through it, from entering the interior of the eye, otherwise than through the pupil. (5) The iris-pigmentation is essential for retinal shading. Albinotic eyes are largely due to iris-translucency. (6) The alternation of contraction and dilation of the pupil induces changes of stimuli and rest. (7) The natural pigmentation of the skin gives added exclusion of useless and harmful light. (8) The eyelashes screen the light and shade the pupil, at the same time allowing enough light to pass to give a useful image of an object above or below the eye. (9) Winking completely shuts out the entire retinal stimulus for an instant, thousands of times a day. (10) Binocular vision also serves more than would the cyclopean eye in breaking up the continuance of the stimulus of the retina upon any one spot. (11) Of still greater importance are the incessant movements of the eyes, those of the body and head aiding. (12) The eyebrow shades the eye. No room should be lit so that the individual lights are visible. Illumination should be transmitted, dissipated, and reflected light.

Philadelphia Medical Journal, December 13, 1902.

A Plea for the General Employment of Credé's Method.—N. J. Weill calls attention to this too-little practised but excellent means of prevention at our disposal. Now and then comes a report of an unpleasant though not serious conjunctivitis set up or excited by Credé's practice. All cases of innocent conjunctivitis occurring in practice, in which Credé's method has been used as a preventive, can not be justly attributed to the silver, since many vaginal secretions and antiseptic douches are capable of setting up conjunctivitis in the new-born. The physician should have the necessary slides or cover-glasses, with implicit directions as to the preparation for the examiner. The writer closes with an appeal to instil, according to Credé, a drop of a 2-per-cent. solution of silver nitrate into the eyes of the new-born.

The Lancet, December 6, 1902.

Eosinophilia Associated with Bilharzia Disease.—The patient of A. E. Russell was a man of twenty-five years, who had served in the African war, drinking at times of polluted water. He developed a cough and had a slight hæmoptysis. A month after reaching home he passed blood in the urine. The latter showed typical bilharzia ova and small patches of bladder cells. Counts showed 10,000 leucocytes, 4,770,000 red cells per cu. mm. with 60 per cent. of hæmoglobin. Eosinophiles were present in from 23 to 33 per cent. The case is of interest as showing the occurrence of a well-marked eosinophilia in many of the diseases of man caused by parasites, and is only the second on record so far as concerns the bilharzia disease.

A Case of Concealed Accidental Hemorrhage.—J. W. Ingles reports the case of a full-time healthy primipara of forty years. When called to the labor he found, on applying his hand to the abdomen, an obscure feeling of crepitus similar to that felt in a severe bruise with extravasated blood. A few drops of blood had escaped from the uterus. The patient had worked hard the day previous about her household duties. On examining per vaginam, the passages were found to be normal; the os was normal and dilated to admit two fingers, while nothing unusual was to be felt in the vicinity. The presentation was normal and the membranes were intact, but the fingers after the examination had on them a little fresh blood. There was no hemorrhage taking place externally. Taking into consideration the patient's previous day's work, her pulse, her pallor (which was not abnormal, but for the fact that the woman in health was "full-blooded"), the fact that her pains were not in character what they ought to be according to the patient's statement, the freshness of the few drops of blood which were external, and more especially the slight obscure crepitus on palpation and the globular appearance of the abdomen, it was concluded that this was a case not often met with by the general practitioner—namely, a case of concealed accidental hemorrhage. Digital dilatation of the os was at once commenced, and, as soon as possible, the membranes were ruptured and liquor amnii escaped with blood. By this time the pulse was occasionally imperceptible, so forceps was applied, and when the first blade passed the head blood poured out; the child was immediately delivered, and along with it the cord, membranes, and placenta came away all in one. The child was dead and the placenta looked as if it had been separated for some time. Following this the uterus, which was full of large clots, was emptied of blood and well contracted by manipulation and ergot. No blood was lost after this, and contraction was obtained immediately the uterus was emptied. The patient had the same appearance and her mind remained very clear. Her pulse varied, being sometimes perceptible and sometimes imperceptible. Stimulants and saline rectal injections were given, but the patient gradually became pulseless and collapsed.

A Note on the Causation and Treatment of Thrombosis Occurring in Connection with Typhoid Fever.—A. E. Wright and H. H. G. Knapp have made a series of experiments to determine coagulation time and blood-content in calcium salts in the acute stage of typhoid fever during convalescence, and in normal persons. During the acute febrile stage there is a diminished coagulability, and this may explain the serous hemorrhages occurring from comparatively small intestinal lesions. During convalescence there is a marked increase in coagulability. A similar increase of calcium salts is noticed in convalescence. The therapeutic inference is the advisability of administering at any time, when coagulability may be above normal, some agent that may diminish this hypernormal state, and thus oppose an obstacle to the deposition of fibrin and consequent thrombosis. Citric acid was the agent selected by the authors, and they present certain statistics, showing how the administration of this remedy in certain cases was followed by a decalcification of the blood and a consequent diminution of its coagulability. In searching for the cause of thrombosis in typhoid fever, the attention of the authors was fastened on the fact that their tables showed that the amount of calcium salts in typhoid convalescents was greatly in excess of that in the normal blood.Th is fact suggests that the increased coagulability during the convalescent stage may be depended upon an excess of lime salts. Evidence pointing in the same direction is afforded by the circumstance that the blood coagulation times of typhoid patients, after the content of their blood in lime salts had been brought within the limits of the normal, were longer than those of normal bloods, instead of being shorter, as we should expect them to be if the increased coagulability were dependent upon an increase in the albuminous elements which enter into the composition of the fibrin. When we consider the source of the excess of lime salts which appears to be present in the blood of the typhoid convalescents, we must conclude that such excess comes from cows' milk, so extensively used in the typhoid dietary. Hence we may, in addition to giving the citric acid, decalcify the milk by adding the proper proportion of citrate of soda, say one to two scruples to the pint of milk.

British Medical Journal, December 6, 1902.

Note on a Case of True Intestinal Sand.—C. H. Bedford records this case. The patient was a woman of forty-four years, with a very marked history of gout. Constipation with mucus was present. There was a distinct attack of mucocolitis coincident with the passage of the sand. There was no colic, vomiting, or distension. The urine showed much albumin, with a few casts. She had been for some months on milk and farinaceous diet when the sand was passed. Treatment was by preparations of lithium, occasional saline purgatives, and colchicum and potassium iodide in mixture. The deposit passed consisted of cocci and bacilli, moisture, calcium phosphate, calcium carbonate, magnesium phosphate, and organic matter. The condition would appear to be closely related to gout and to be favored by a milk diet.

An Address on Acute Manifestations of Chronic Disease.—J. Mitchell Bruce says that what we commonly call "acute disease" is, in many instances, nothing else than an acute illness in the course of a chronic disease. This manifestation is often difficult to diagnose. We are often blinded to the truth by the circumstances attending an acute illness. Still more readily may we forget the chronic element if the acute element take the form of a substantive disease, so-called. The writer cites cases showing acute phenomena in the course of chronic disease—hemorrhage, abdominal pain, vomiting, and collapse. They should not deceive us with the use of proper care and judgment. But when acute manifestations of chronic processes possess all the characters and the importance of independent diseases, they readily monopolize our attention, and lead us astray in diagnosis and treatment. Haste, thoughtlessness, and clinical inattention should be guarded against. Proper investigation of an acute illness often directs attention to the existence of a disease that has lasted for an indefinite length of time, but which has been entirely unsuspected, and which it is of vital importance that we should recognize. The immediate prognosis, like the immediate treatment, of acute illness cannot be expected to be successful unless the true relations of the attack be observed and appreciated, as with the immediate, so is it with the remote prognosis and the practical applications of it. These acute attacks offer a useful opportunity of striking at and arresting the primary disease in its course, while it is still comparatively slight.

On Colon Catarrh.—T. Stacey Wilson includes under this head the following morbid conditions: (1) Simple acute catarrhal colitis; (2) Subacute and chronic simple catarrh of the colon intermediate between one and three; (3) The so-called "mucomembranous colitis." also called "membranous colitis;" (4) Mucous colic; (5) True catarrhal typhlitis. The various types are found to pass into one another. Catarrhal condition of the colon manifests itself by altered function of two kinds. (1) Abnormal secretory activity. (2) Abnormal motor activity. With regard to the mucus passed by the bowel, there is very great variety. Catarrh of the colon is due to irritation. The irritant may be mechanical or chemical or of a more complex nature. A most important part is played by gout and the arthritic diathesis in the etiology of the subacute and chronic forms. Another possibility as to the causation is that microorganisms play an important part in the intestinal irritation. It is probable that the neurotic element is only an early symptom of the complaint and not its cause. The primary symptoms of colon catarrh are: Excessive secretion of mucus; excessive irritability of the muscular coat of the colon, causing it to harden and become palpable. 3. Constipation, due probably to both altered secretion and altered motility of the colon; pain—often colicky—and tenderness of colon: nervous phenomena, especially well-marked mental depression,often hypochondriasis, sometimes true neurasthenia. If the case be recognized early enough, and appropriate treatment by diet and medicine be given, the prognosis as to complete recovery is very satisfactory. The key to treatment of this disease is the recognition of its relation to gout and the "uric-acid" diathesis, and also that it is a catarrh of the colon. The salicylates should be given. All foods liable to leave an indigestible solid residue should not be touched. So brown bread, porridge, figs, etc., should be avoided. In old cases, enemata of saline solution or boracic acid are sometimes valuable. It is most important to recognize cases early.

Deutsche medicinische Wochenschrift, November 20, 1902.

Schueller's Parasite of Carcinoma.—Heinrich Mohr disagrees with Völcker, who holds that the bodies described by Schueller in carcinomatous tissue are none other than cork cells which have become accidentally lodged in the tissue during its manipulation in the laboratory. A morphological comparison of Schueller's parasites and cork cells shows that while they possess many features in common, yet the large size of the capsules of the former serve to absolutely distinguish them from the latter. Furthermore, a large number of carcinomatous sections have been prepared by Mohr, with the employment of a technique which absolutely excluded any possible contamination with cork or cork cells, and in all of these sections the presence of Schueller's parasites was demonstrated. It is believed that these observations will definitely negative the contention that these parasites and cork cells are one and the same.

Relations between Tuberculosis and Carcinoma.—Ed. Aronsohn draws attention to the close relations which exist between tuberculosis and carcinoma and reports twenty-two cases, which show that carcinoma in one generation is frequently followed by tuberculosis in the next. That the reverse also occurs is probable, but no statistics relative thereto have been gathered by the author. Furthermore, lupus may, probably, be regarded as a transitional stage between tuberculosis and carcinoma, for while, on the one hand, histologically it is essentially tuberculous in form, on the other hand it is a well-known fact that under certain unknown conditions typical lupus lesions may be transformed into carcinomatous tumors. The development of tuberculosis in the offspring of carcinomatous parents may be accounted for in several ways, but under any circumstances hereditary nfluences must play a most important part. In the present state of our knowledge concerning the etiology of carcinoma it is, of course, impossible to affirm with positiveness that the carcinomatous microbe is transferred in utero to the offspring in the body of which, on account of new environments, it becomes biologically altered and gives rise to tuberculous lesions; yet when all the facts are in, it is not without the range of possibility that such will be found to be the case. However this may be, there is already abundant evidence to show that the etiological conditions which underlie tuberculosis and carcinoma are closely related, and that, under certain unknown conditions, by the influences of hereditary transmission, they may become interchangeable.

Berliner klinische Wochenschrift, November 24, 1902.

Atonic Dilatation of the Œsophagus.—Max Lewinson reports a case which is of interest because dilatation of the œsophagus is rarely met with, except as the result of lesions which give rise to a permanent contraction of this tube. In such cases the dilatation occurs immediately above the point of constriction. In the case reported the etiology is not clear. The first symptoms were pain in the chest after eating, and a feeling of discomfort after eating, and a sensation as though the food has not passed from the œsophagus into the stomach. There soon developed periodical attacks of vomiting, which resisted all treatment. The vomited food was voided soon after eating, and was unaltered in appearance, not having been in the least acted upon by the gastric juice. Physical examination of the chest failed to reveal any abnormalities, and since the clinical symptoms plainly pointed to a dilatation of the œsophagus, it was decided to administer to the patient a "test meal," and examine the condition, by the aid of the stomach sound. One-half an hour after the "test meal" was given the sound was introduced into the œsophagus, and slowly passed downward. When it had been passed downward for 20 cm. undigested portions of the "test meal" be gan to flow through it. This continued until a depth of 50 to 52 cm. was reached, when the flowing stopped, and a slight resistance was encountered. On making firm pressure the point of the sound slipped into the stomach, which was immediately followed by the evacuation, through the sound, of portions of the meal, which were undergoing gastric digestion. Many examinations similar to the above were made and identical results obtained.

Metabolism in Chronic Tuberculosis.—J. Mitulescu, after a review of the pathological lesions of tuberculosis, in particular pulmonary tuberculosis, and a study of the nitrogen and phosphorus metabolism occurring in the same, concludes that the endeavors of the body to combat the infection are both mechanical and chemical in nature. The mechanical process consists in the formation of a barrier of cells of various kinds around the tuberculous bacilli, which is more or less efficient in preventing the spread of the bacilli from their primary location in the tissues to other regions of the body. The chemical process consists in the production by certain body cells of secretions, some of which are destructive of the infecting bacillus, while others neutralize or destroy the bacillary toxins produced. The body is able to successfully combat the infection just in proportion as these processes are effectively and continuously maintained. From these data it is evident that these processes can be effective only when the involved body cells possess a satisfactory degree of vitality. Such vitality is only possible when these cells possess a satisfactory nutrition. Under-nutrition of these cells must inevitably lead to a reduction in their vitality, and a consequent inability to cope with the infective process. In the presence of infection, a double work is thrown upon the body cells: (1) They must, as under normal conditions maintain their nutrition. This they do, as observation has shown, by a synthetic process. That is to say, they cannot directly assimilate the nutritive principles present in the blood and lymph, but are compelled to form the nucleoproteids, which constitute a large portion of their substance, from the albumins and nucleinic acids (xanthin bases + phosphoric acid), which are brought to them by the circulating fluids, and which originate during the process of digestion in the intestinal tract. (2) They must produce the bactericidal and antitoxic secretions which directly assail the infecting bacilli. Since the satisfactory execution of the first of these tasks is absolutely essential to the proper performance of the second, observations which determine its actual status in any given case are all important in the prognosis and treatment of the same. By a comparison of the daily consumption by the patient of nitrogen and phosphorus with the total daily excretion of the same elements in the urine and fæces were are enabled, in great measure, to judge the status of the cell metabolism. If the excretion exceeds the consumption, we know that the cells are suffering in nutrition, either because of their reduced vitality and consequent inability to assimilate the same, or because of the increased demands made upon them in their fight against the infection. Either of these conditions must inevitably lead to the same result, viz., an inability of the cells to successfully combat the infection. Observation has shown that in acute and the first stages of chronic tuberculosis the excretion of these substances almost invariably exceeds their consumption. In chronic tuberculosis, as the disease progresses, the excretion and consumption become more nearly equalized, especially in those cases in which the progression is favorable. If hemorrhages occur, the excretion of nitrogen and phosphorus in the urine and fæces becomes temporarily far less than the consumption, because of the large amount of these substances, which are lost in the evacuated blood. In all cases, however, an increased excretion over consumption signifies either that the cells are in a state of undernutrition, or that they are being overworked. This determination, if the observations are being carefully and frequently made, is one of the first signs that the body is losing ground in the conflict. In advanced cases this condition is much accentuated, because of the mixed infection, which is nearly always present.

Munchener medicinische Wochenschrift, November 25, 1902.

Gelatin Treatment of Melæna Neonatorum.—E. Oswald does not think that thus far a sufficient number of cases have been treated with subcutaneous injections of gelatin to warrant the high opinion of this treatment, which is held in many quarters. The author reports five cases, two of which were treated with gelatin and three by other means. The two treated with gelatin recovered, as did also two of the others. The child which died only weighed 1,750 grams at birth, was in very poor general condition, and would have certainly died under any form of treatment. It is evident from these two and other reported cases, which have been treated by gelatin, that the same is an efficient means of combating the disease, but it must be borne in mind that a fair number of cases which are treated by other means also survive, so that it should not be too quickly taken for granted that gelatin solution, administered subcutaneously, acts in the nature of a specific in melæna neonatorum.

Operative Treatment of Pulmonary Tuberculosis.—A. Landerer writes in favor of the operative treatment of tuberculous pulmonary cavities. It is not to be supposed that this treatment is in any sense curative, but it is certain that in many instances life is prolonged, and the local and general symptoms much improved. In all cases which are thus treated, the operation should be conducted as quickly as possible, and all hemorrhages from the intercostal vessels should be avoided. In the resection of the ribs it is important that an ample amount should be removed, so that easy access should be obtained to all portions of the cavity. On closing the wound the same should not be entirely sutured, since experience has shown that when this is done, deep suppuration is very liable to occur. In the after-treatment morphine should be given in sufficient doses to quiet the cough, since the same causes much pain, and if excessive is liable to give rise to an aspiration pneumonia. In the choice of patients for operation acute cases are to be entirely avoided. The most suitable are those in which the tuberculous process is stationary, or but very slowly progressive. Nine cases are reported in detail

Phagocytosis, Synthesis, and Other Intracellular Processes.—J. Arnold does not think that soluble substances are always taken up by the leucocytes by the process of phagocytosis. In phagocytic cells, such as eosinophiles which have been placed in contact with fat, observation has shown that, while a certain portion of the fat is undoubtedly taken up by a phagocytic process, there are still other portions of fat which are so closely combined with the eosinophilic granules that it seems certain that this fat is produced synthetically in the cell. This is not to be regarded as a degenerative condition, since such eosinophiles are in no way to be regarded as in a stage of degeneration. Furthermore, when fat is is brought in contact in excessive amount with the tissues, other cells, such as the epithelial, which are able to exert no phagocytic processes, show after a time an abundant presence of fat in their protoplasmic interior. Certainly in these cases the presence of the fat must be due to a synthetic process. Similar observations have been made with respect to the presence of the various iron compounds in cells, so that it is evident that in many instances the presence of soluble foreign compounds in the leucocytes is not to be ascribed to their phagocytic action.

A Case of Right Spontaneous Pneumothorax.—H. Maillart and A. Lasserre declare that the cases of spontaneous pneumothorax—that is, in subjects with pulmonary lesions that have not manifested their presence by appreciable troubles—are not numerous in literature. They report the case of a young man who was in a condition of apparent health, but who was suddenly attacked by a right pneumothorax, accompanied by extreme suffocation. The dyspnœa and pain rapidly decreased in the space of one or two days. The general condition remained good, and the temperature was not elevated above normal. The first radioscopical examinations showed that the lung was reduced to its minimum volume. It gradually attained its original dimensions, while the neighboring organs, which had been pressed out of position, returned to the normal condition. About three weeks after the onset of this trouble the patient left the hospital. The right pleural cavity did not contain a trace of liquid. Twelve days later an examination by the *x*-rays showed a slight effusion in the costo-diaphragmatic sinus. There was no fever. The general condition remained good up to the time of his final departure from the hospital, about nine weeks after the onset. At that time the effusion had almost disappeared. The patient has continued to improve, and has never suffered from any subjective troubles on the part of his right lung.—*Revue Médicale de la Suisse Romande*, November 20, 1902.

Society Reports.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Proceedings of the Thirtieth Annual Meeting, Held in New Orleans, La., December 8, 9, 10, 11, *and* 12, 1902.

The association convened in Tulane Hall under the presidency of Dr. Henry D. Holton of Brattleboro, Vt.

The opening address of welcome was delivered by Rev. Max Heller of New Orleans.

After the transaction of routine business, the reading of papers and reports was begun.

Report of Committee on Disposal of Refuse Materials.—This was read by Dr. W. C. Woodward of Washington, D. C., a member of the committee. The report stated that the present condition of the art of disposal of city refuse had not advanced materially in the last year. Many of the largest cities in America had reduction plants for the extraction of the grease with more or less success. The latest, and in some parts of the country still the most common, method of disposal, namely, that of feeding kitchen garbage to swine was now earnestly advocated by a prominent health officer, although most ardently opposed by most sanitarians for many years. It was advocated because under many conditions it was not unhealthful, if properly conducted, and it was more economical in smaller communities than any other method. The Berlin proposition of converting kitchen garbage into compost had not yet been sufficiently tried. The results with this method in this country did not seem promising, except where the soil was quite barren and the cost of labor very low.

Report of the Committee on Animal Diseases and Animal Food.—In the absence of the chairman of this committee, the report was read by a member of the committee, Dr. M. P. Ravenel of Philadelphia. Reference was made to researches with regard to the communicability of human tuberculosis to animals. The experimental work of Ravenal, Mohler, De Jong, Delepine, Orth, Stenstrohm, Fibiger and Jansen, Max Wolff, Nocard, Arloing, Behring, and a number of other investigators, was referred to at length, and these investigations were sufficiently numerous and harmonious in the results to establish the following conclusions: (1) The bacillus tuberculosis found in human tuberculosis differed greatly in its pathogenic powers as obtained from different cases. (2) Two types of tubercle bacilli might be obtained from man, namely, one which was somewhat difficult to cultivate, which grew slowly, and the bacilli of which are short, stubby, and free from beading—the so-called bovine type; and the second, which was quite easily cultivated, grew rapidly, was longer, thinner, and inclined to show beading and curved forms—the so-called human type. (3) Virulent cultures might be obtained from both of these types, which, when inoculated, according to the methods used by Koch, and upon the species of animals specified by him, produced progressive and fatal tuberculosis. (4) The contention that human tuberculosis could not be transmitted to asses, sheep, goats, and especially to cattle, had been completely disproved. (5) Koch's failure to produce tuberculosis in the animals named with bacilli from human sources was probably due to the use of bacilli of low pathogenic powers. The report then discussed at length investigations as to the transmission of bovine tuberculosis to man, mentioning the experimental work recently done in this line. The results of these investigations showed: (1) While the bacilli of human tuberculosis were found of feeble virulence for cattle, there was a considerable proportion of cases in which these bacilli were virulent for cattle as well as other animals. (2) Bacilli of both the bovine and human type had been obtained from cases of human tuberculosis. (3) Bovine bacilli introduced into the human tissues by accidental inoculation, if left, multiplied, and produced disease at the point of inoculation and even recovered after a considerable time with their vitality and virulence unimpaired. (4) Various statistical studies indicated that a considerable proportion of cases of human tuberculosis, and, particularly, with children, originated from the ingestion of the bacilli with contaminated food. It appeared to the committee, therefore, that the conclusions of Koch, announced at the British Congress of Tuberculosis, to the effect that bovine and human tuberculosis were different; that human tuberculosis could not be conveyed to cattle, and that man was insusceptible to bovine tuberculosis, were disproved, and should no longer have weight with sanitarians. The evidence adduced indicated that greater care should be exercised to prevent infection with bovine tuberculosis, and particularly to guard children from tuberculous milk.

Sanitary Measures Proposed to the Mexican Railway Companies.—Dr. Eduardo Licéaga, President of the Superior Board of Health of Mexico, read a paper on this subject. The measures urged were: (1) To increase the number of cuspidors, and furnish them with disinfecting solutions capable of destroying the tubercle bacilli. (2) Place in conspicuous places placards containing the following: Please spit exclusively in the spittoons, as otherwise the germs of infectious diseases, especially those of tuberculosis, will be carried into the air. (3) Until paddings of the cars were changed for other and more convenient drapery, a wise plan would be to disinfect the car every time it was unoccupied with a solution of formaldehyd, which would not alter the condition of the cloth nor its color. (4) Disinfect all sheets and pillow cases before sending them to the laundry. (5) Also disinfect the tapestries and couches. (6) Keep the car as clean as possible, and especially the closets and urinals. The railroad companies in Mexico considered the above suggestions practical and promised to enforce them.

Coöperation Essential to Progress in Vital Statistics.—Dr. Cressy L. Wilbur of Michigan presented a paper on this subject in which he said we were at the beginning of a new era when, for the first time, in the history of the country, there was an opportunity for continued systematic coöperation between the permanently organized department of the national government and the various State and municipal systems of registration to the end that accurate and uniform statistics of mortality might be obtained for the United States and made available for the use of all public health offices.

Vital Statistics: A Plea for Actuarial Administration and Control of the Great Resources of Preventive Medicine.

The author of this paper, Dr. John S. Fulton of Baltimore, said the federal census, which, being now maintained as a permanent part of the national government, should: (1) Be at the approach of another census year better than ever prepared to rapidly and accurately count the people making notes of all the data needed for statistical purposes. (2) It should make such *ad interim* studies of the births and deaths occurring in non-registration areas as would serve for the better correction of the enumerators' returns for the census year. (3) It should commit all vital returns to the hands of a trained medical statistician who understands the moods and tenses of vital mathematics. Local registration should recover (*a*) records of deaths made at the time and place of their occurrence, by the most competent persons acquainted with the facts, including a medical certification of the cause of death, the making and filling of such a record being, in every instance, an indispensable preliminary to the disposal of the dead body. (*b*) Records of birth, secured by the payment of fees, by every appeal to private interest and public necessity, including, if possible, conditioning of certain privileges of citizenship upon recorded evidence of attained age. (*c*) Records of marriages and divorces, with all such items of information as had statistical importance. (*d*) Records of sickness, including all cases of those infectious diseases which fell within the provisions of the notification laws, all cases of sickness which came under study in the public health laboratories, all sickness which was relieved at public cost, and all sickness falling under the observation of inspectors of schools, tenements, and factories. The data of vital statistics should be systematically utilized, not only for the broader purposes which had grown into common use, but for the minuter inquiries to which such records in large numbers and of great variety were adapted.

Dr. Luis E. Ruiz of Mexico presented a paper in which he spoke of the period in which every contagious disease could be transmitted, and also of the period in which every sick person was dangerous to healthy persons near him.

Dr. José P. Gayón of Mexico read a paper in which he spoke of the transmission of pathogenic fungi by flies and mosquitos.

Dr. Jesús E. Monjaras of Mexico discussed the principal causes of infectious diseases and the chief means of guarding against them.

At the evening session of the first day, addresses of welcome were delivered by Mayor Paul Capdevielle on behalf of the city, and by Hon. Jared Y. Sanders, Speaker of the House of Representatives, on behalf of the State. These addresses were responded to by President Holton.

Presidential Address.—President Henry D. Holton then delivered his address. He reviewed the status of sanitation in the United States, saying the most wonderful progress had been made along all sanitary lines. Much of it was the result of the work of members of the association. In speaking of yellow fever, he said we should recognize the great courage of such devotees of science as Drs. James Carroll and Jesse W. Lazear. The practical results of work done in regard to yellow fever had been evidenced this past summer; not a case of this disease had originated in the island of Cuba for the past fourteen months, and the quarantine period had been shorter by three months. He referred feelingly to the deaths of Drs. Walter Reed, Robert C. Kedzie, Albert L. Gihon, Thomas J. Turner, John P. Kimball, Francis W. Lewis, Geo. E. Tyler, and Wyatt Johnston.

Speaking of sanatoria for tuberculosis, he said that when education had advanced a step further, and the public came to appreciate that sanatoria for the tuberculous opened to such as had unfortunately become infected, the most promising avenue of escape from certain death, at the same time it was an additional safeguard against the spread of the disease, then would the *vox populi* demand that justice be done the impecunious sufferers in the establishment by the State of institutions where, in the earliest stage of the infection, they might be placed, and thus given all possible aid to recovery and the enjoyment of social and productive citizenship.

In alluding to smallpox, he said the modified virulence and the reduced power of infection had been seized upon by antivaccinationists and the ignorant as an argument against vaccination. The association had been striving for many years for the establishment of a public health service, and the medical profession was to be congratulated that at last their efforts had been crowned with success. While all that was desired had not been granted, yet a substantial, and, in many ways, a satisfactory organization had been effected. He congratulated Dr. Wyman on the enlarged opportunities presented to him to develop upon a scientific basis a service of varied functions which shall equal in original research and demonstration any similar service in the world.

Report of Committee on Public Health Legislation.—This was presented by the Chairman, Dr. U. O. B. Wingate of Milwaukee, Wis. Representatives from various State boards of health and State quarantine officials met in Washington with the supervising surgeon-general of the Marine Hospital Service, and the matter was carefully considered, and finally a compromise was effected, changing the name of the Marine Hospital Service to that of the Public Health and Marine Hospital Service. A copy of the law was submitted with the report. The law provides for an annual conference of the health authorities of all the States and Territories and the District of Columbia, and that it shall be the duty of the surgeon-general of the service to call a conference upon application of not less than five State or Territorial boards of health, quarantine authorities, or State health officers. It was hoped that this measure provided a foundation upon which might be built up a national health service, such as the intelligence of the people and the age in which we are living demanded.

Experiments in Disinfection with Formaldehyde Gas.—Dr. M. P. Ravenel of Philadelphia read an exhaustive paper on this subject, in which he detailed his experimental work with this gas. He drew the following conclusions: (1) Formaldehyde is justly entitled to the high position which has been given to it as a disinfectant. (2) Special apparatus, while useful and convenient, is not absolutely necessary for the successful application of the gas. (3) The germicidal power of formaldehyde gas is dependent on certain factors which, as yet, are imperfectly understood. Other things being equal, moisture and temperature are the most important of these factors. (4) In practice every operation should be controlled by cultural experiment, and no room which has been exposed to infection should be considered as disinfected unless control cultures exposed in various parts of said room are shown to have been destroyed.

Report of Committee on Disinfection and Disinfectants.—In the absence of the chairman, this report was presented by Hibert W. Hill of Boston. A careful examination of articles published both in America and in Europe had failed to reveal the discovery of any new disinfectant or process of disinfection of great practical value to public health officers during the last year. As to gaseous or room disinfection, formaldehyde still held the first place in efficiency. There had been a return to a certain extent to the use of sulphurous acid, owing to its stronger action upon insect pests, but all the new experiments showed clearly that it was a far weaker disinfectant than formaldehyde, and could not be depended upon, except in a few limited cases. Gaseous disinfection, as the great panacea for preventing the spread of contagion, had been considerably discredited by recent experiments, but the committee were strongly of the opinion that when properly carried out, it was an important and effective aid in public health work, and would continue to be, and that formaldehyde was by far the best agent to use in carrying it out. In using formaldehyde two things should be provided for: (1) A sufficiency of water in the air of the space to be disinfected; and (2) a very rapid disengagement of the the gas. Most forms of apparatus failed in one or the other of those points. The work of Robinson and Hill, members of this committee, clearly showed that not only did efficiency depend upon them, but by properly observing them much time and material could be saved. The disinfection of the future must be simple, short, and sharp.

Report of the Committee on National Leper Homes.—In this report the chairman, Dr. Henry M. Bracken of St. Paul, Minn., said, among other things, that after carefully studying facts it would appear that provision for the care of lepers in Canada was an inheritance rather than a product of legislation; that the care of lepers in Mexico began with the invasion of Cortés, and that the methods of caring for them had been but little, if at all, improved upon in that country since his time. That provision for the care of lepers in Cuba was made at an early date by a Jesuit with philanthropic tendencies. Of all the countries embraced in the association, the United States was the only one that had made no provision for its lepers. The commission appointed by the

Marine Hospital Service recommended one, or preferably two, national leprosaria for the care of these unfortunates in the United States. It recommended the selection of sites covering broad areas in healthful localities, where the lepers could have unlimited out-of-door exercise and occupation. It recommended that these homes should be made attractive and comfortable, so that the unfortunate victims of this disease, instead of hiding their condition might make it known and request admission to these public institutions. With present knowledge of leprosy, and the methods employed in care of lepers, the committee advised that the resolution of last year be reaffirmed. This resolution, in substance, favored the establishment of national leprosaria, which might serve not only as a refuge for lepers, but also as a home and hospital, making their lives tolerable as far as possible, furnishing employment to those who were able to work, and giving skilled medical care to all cases, with the intent of possibly curing some, and making the road to death less wearisome and painful than it now was to others.

Dangers to the Public Health from Illuminating and Fuel Gas.—This report was read by the Chairman of the Committee, Dr. Samuel H. Durgin of Boston. In pursuing an inquiry into the danger to health by illuminating gas, it had been the purpose of the committee to consider not only the question of its poisonous effect, as observed from the ordinary clinical standpoint, and of the frequency with which the people were exposed to the effects of this agent, but also to show, from carefully-conducted experiments upon human subjects, just what physiological changes were produced by long and short exposures to small amounts of the gas, and to what extent the observed changes were continued or permanent. It was shown by investigations that the common condition of gas-pipes and fixtures was very poor, the moderate small leaks very numerous, and that a moderate increase of pressure in the fixtures above the normal gas pressure, produced leakage in 89 per cent. of all the houses examined. It was also shown that the number of fatalities from illuminating gas was not only large, but was increasing from year to year. In order to ascertain to what extent the medical profession in Boston had recognized cases of acute and chronic poisoning by illuminating gas, he sent out letters to twenty-two hundred physicians, asking for their personal experience in such cases. He received replies from 460 physicians; 246 of them reported no experience; the other 214 reported 1,025 cases of acute poisoning; 374 of these resulted fatally; 288 were found dead, and 86 lived from one hour to twelve months; 623 made complete recovery in periods varying from a few hours to three years; 28 made partial recovery, while under observation, of from three weeks to twenty-one months.

The symptoms reported in the chronic cases were practically the same as those reported in the acute cases.

Symposium on Yellow Fever.—Annual Report on Yellow Fever in Mexico.—This report was read by Dr. Eduardo Licéaga of Mexico, who presented statistics of the spread of the disease along the Mexican coast. The recent epidemic in Vera Cruz developed 877 cases, being the most severe in the country. His report showed that 873 cases were on the Gulf Coast, while only twenty-seven cases had been reported on the Pacific Ocean Coast. The epidemic in the State of Vera Cruz had been diminishing. The report mentioned the number of cases reported by States where points of infection had been found. The death rate was low, and had been held down by the successful management of the disease. The government of the State of Vera Cruz had adopted up-to-date sanitary measures for the prevention of the spread of yellow fever.

Yellow-Fever Epidemics in Orizaba, Mexico.—This paper was read by Dr. Narcisco del Rio of Mexico. The author related with particularity the history of the spread of the disease in his section. The inevitable conclusion was that the mosquito had been carrying his dangerous freight from place to place in the Orizaba section, thus causing the spread of the disease. The essayist found, in tracing the disease closely, that a coachman, who had hauled one sick person, had been bitten by a mosquito and was soon taken down with the fever. They at once took the necessary means to meet this agency of transmission, and after that were successful in checking the spread of the disease.

Yellow Fever.—Dr. John W. Ross, U. S. Army, gave at length his reasons for believing that the only way in nature for yellow fever to be contracted by man was from the mosquito. He recommended the following measures against the propagation of yellow fever through mosquitos: (1) To prevent those insects from stinging yellow-fever patients. (2) To destroy, as far as possible, the mosquitos which have been infected. (3) To consider any place unsafe so long as the last mosquitos which have stung yellow-fever patients may be alive in it. He stated that the clear-cut, scientific observations and classical contributions of Surgeon H. R. Carter of the United States Marine Hospital Service, showing the interval (about two weeks) which occurred in houses between the first (infecting) case and the first group of cases, secondarily infected, impossible to explain by the theory of fomites, were now readily understood in the light of present knowledge of the elaboration of the yellow-fever poison in the body of the mosquito, that process requiring not less than twelve days.

Concerning the Method of Transmission of Yellow Fever from Man to Man.—Dr. William C Gorgas, U S. Army, contributed a paper with this title. The author enunciated practically the same views that have been published in previous papers on this subject by him. As to whether the disease might be transmitted through fomites from man to man, or whether by the bite of fever-infected mosquitos, the decision depended on what steps should be taken to confine yellow fever when it made its appearance, whether a fight should be made against the mosquitos, or whether cargoes and vessels, and all things that were to be transferred from point to point, in which fomites could be conveyed, should be thoroughly disinfected. If the germs of the disease could not be transferred in fomites, then the disinfection of vessels and cargoes was unnecessary. The only measures necessary would be the destruction of infected mosquitos and the care of persons who might transmit the germ to the mosquitos.

Dr. Manuel S. Iglesias of Mexico discussed the disinfection of railroad cars as a precautionary measure against the propagation of yellow fever by mosquitos; while Professor Geo. E. Beyer of New Orleans related his investigations regarding yellow fever in Vera Cruz.

Dr. Edmond Souchon of New Orleans did not antagonize the theory of the transmission of yellow fever by mosquitos, but he did not believe that we were prepared to say that the mosquito was the only mode of transmission of the disease. After a close and careful study of the question, he had reason to believe that there was some other means of transmission. What it was he could not say. It might be fomites, or something we knew nothing about.

Dr. Hamilton P. Jones of New Orleans, who was in charge of the Beauregard yellow-fever hospital in this city in 1896, said that, despite the fact that 300 people were exposed to mosquitos as transmitters of the disease, as well as fomites, not one of them had been stricken, and he was still in the dark as to the doctrine of transmission of the disease.

Dr. John Guitéras of Havana said that Havana was the first of the large cities which had appreciated the necessity of adopting precautionary measures against the mosquito, and was first to do so. He then explained the prophylactic measures which were carried out in Havana.

Dr. E. R. Carter of the Marine Hospital Service expressed the idea that if the disease was conveyed to an animal host, it was conveyed there by a parasite. He said the conveyance of the disease might occur in two ways by fomites: (1) directly to the person, and (2) through an infected atmosphere.

Dr. QUITMAN KOHNKE of New Orleans, after mentioning the fact that the Board of Health was doing all in its power to guard against the disease, said that still more strenuous efforts should be made to keep it from coming to New Orleans from infected ports. If the disease was conveyed by fomites as well as by mosquitos, it was logical to conclude that there was a greater danger than if it was conveyed alone by the stegomyia fasciata.

SECTION ON BACTERIOLOGY AND CHEMISTRY.

The Occurrence of Tubercle Bacilli of Exalted Virulence in Man.—The author of this paper, Dr. M. P. RAVENEL of Philadelphia, stated that the occurrence of tubercle bacilli in man which had a high degree of virulence for experimental animals was rare, if one judged by the published reports, and it was still more rare to find cultures which were highly pathogenic for cattle. So marked was the difference in pathogenic power of cultures isolated from man on the one hand, and from cattle on the other, that a division into races had been proposed depending on this feature; and Koch held that inoculation of a given culture into cattle would surely show whether it was of human or bovine origin. Believing that bovine tuberculosis was a fertile cause of the disease in milk-fed children, he had for some time past taken every opportunity possible of selecting cultures of tubercle bacilli from the mesenteric glands of those who had died of a tuberculosis which was not clearly of respiratory origin. This had led to the discovery of two cultures, one of which was as virulent for all animals on which it had been tested as cultures obtained from cattle usually were; and the other, while not nearly so virulent, was still much in advance of the usual human culture. The material from which these cultures were isolated was furnished through the kindness of Dr. Alfred Hand of Philadelphia.

Observations on the Morphology of Bacillus Diphtheriæ, Bacillus Pseudodiphtheriæ, and Bacillus Xerosis.—Dr. F. P. DENNY of Brookline, Mass., read this paper, which was based on the study of serial preparations made at intervals from the same cultures.

Bacillus Diphtheriæ.—In young cultures, up to eight or twelve hours, the development was characteristic of all bacilli, and consisted in elongation of the rods and fission. The bacilli would stain evenly. After this time fission ceased in most of the bacilli, and changes took place in the individual organisms. Granules developed; the rods became elongated, and might become filamentous; the protoplasm might break up into segments; true branching might occur, though very rarely, all of which were changes characteristic of the higher bacteria, and especially of the streptothrix. Certain variation in the conditions of growth might hasten or retard these changes. Thus variations in temperature and in the reaction of the media, also symbiosis might prolong the solid-staining stage, and make the diagnosis of fifteen-hour cultures difficult.

Bacillus Pseudodiphtheriæ.—This was like the young forms of bacillus diphtheriæ. It had no stage of development when it grew into long forms like the higher bacteria. On the contrary, the bacilli were even shorter in old than in young cultures.

Bacillus Xerosis.—Young forms were solid-staining, like young bacillus diphtheriæ. In older cultures the bacilli became elongated and the protoplasm would break up into segments; only rarely did granules appear in pure culture. In symbiosis with other bacteria granular forms might appear which resembled bacillus diphtheriæ.

The Use of Immune Serum in the Separation of Typhoid and Colon Bacilli.—Dr. ADOLPH GEHRMANN of Chicago read this paper. The difficulty in the separation of these species was due to the constant tendency of bacillus coli to overgrow bacillus typhosus. The search for specific retaining agents had not resulted in entire success. If an immune serum active for one or the other species could be used to restrain the growth of one, without disturbing the growth of the other, it would be an ideal method of procedure. He related previous experiments along this line. The serum of rabbits immunized against bacillus coli could be used for this purpose, and gave results that were positive by artificial mixtures of the two species. The method could be improved by using the blood of immune animals direct and by rapid cultivation in the incubator. For practical purposes this method was not as yet certain, and the establishment of a control was difficult. On material containing other species the restraining effect of carbolic acid did not disturb the purpose of the blood that was used. Some rather indefinite results on the isolation of typhoid from water had been reported.

An Examination of the Value of Certain Antiseptics Used for the Preservation of Antitoxin and Other Immune Serums.—In a paper on this subject, Dr. JOSEPH MCFARLAND of Philadelphia said this investigation had for its object the determination of the antiseptic and bactericidal values of chloretone, formaldehyde, chloroform, tricresol, and carbolic acid. It had long been believed that the addition of one-half per cent. of carbolic acid and 0.4 per cent. of tricresol, and 0.1 per cent. of formaldehyde would satisfactorily prevent the growth of microorganisms in the serums so prepared. As some of these reagents threw down a precipitate, the question arose whether the reagent itself was destroyed and too little remained to preserve properly the serum. The research was conducted by preparing the serums with the proper proportions of the germicides, then adding known numbers of bacteria and determining the diminution or increase. The results showed that, other things being equal, formaldehyde was preferable to phenol, but objectionable because it did not kill molds. Phenol was better than tricresol, and the recommendation was made that hereafter tricresol be given up as a preservative of the serum.

Formaldehyde.—Dr. H. W. HILL of Boston read this paper. His conclusions were that humidity was an important factor in formaldehyde disinfection. An amount of gas which failed to kill in six hours at 42 per cent. humidity, killed in twenty to forty minutes at 100 per cent. humidity. Considering the unavoidable leaks and absorption of gas by walls, etc., found in practice, practical disinfection required a rapid discharge of gas and high humidity. The best of the generators tested ran not more than 15 c.c. per minute, and the condensed effluent yielded in the first ten minutes only about a 30-per-cent. solution, hence generation by boiling in the ordinary way was too slow. Spraying was somewhat objectionable from the wetting down of the contents of the room. Atomization by steam current under 15 pounds pressure yielded from six to eight times as rapid a flow of full strength, with no polymerizing, and produced a high humidity.

The Diminishing Importance of Public Water Supplies, and the Consequent Significance of Other Factors in the Causation of Typhoid Fever.—This was a joint paper contributed by Professor W. T. SEDGWICK, and Mr. C. E. A. WINSLOW of Boston. The authors undertook to show: (1) That in the State of Massachusetts and in many of the larger cities of the United States the public water supplies were now unimportant as vehicles of typhoid fever. (2) That in cities having pure water supplies the annual curve of typhoid-fever mortality closely followed that of annual temperature. (3) That in urban communities supplied with pure water there still remained a typhoid-fever tax of from fifteen to twenty-five deaths per 100,000 population. (4) That this tax was due not to any peculiar conditions of soil, locality, or climate (endemic factors), but to incomplete disinfection of typhoid excreta with subsequent infection of various articles of food and drink. These factors, when acting upon a few or many persons at one time, might cause obvious epidemics, sometimes large, though generally small; but more often the infection in moving from one point to another followed different and obscure routes for different victims, and hence might be described as prosodemic. (5) That the only remedies for such prosodemic typhoid were absolutely thorough and universal cleanliness and disinfection of excreta.

Officers for the Ensuing Year.—*President*, Dr. Walter Wyman, Washington, D. C.; *First Vice-President*, Dr. C. P. Wilkinson, New Orleans, La.; *Second Vice-President*; Dr. John L. Leal, Paterson, N. J.; *Secretary*, Dr Charles O. Probst, Columbus, Ohio; *Treasurer*, Dr. Frank W. Wright, New Haven, Conn.

Officers of the Bacteriological and Chemical Section.—*Chairman*, Dr. H. L. Russell, Madison, Wis.; *Vice-Chairman*, Dr. V. A. Moore, Ithaca, N. Y.; *Secretary*, Mr. G. C. Whipple, Brooklyn, N. Y.; *Recorder*, Dr. Henry D. Pease, Albany, N. Y.

Place of meeting, Washington, D. C., 1903.

THE PRACTITIONERS' SOCIETY.

174th Regular Meeting, Held on Friday, Nov. 7, 1902.

Joseph D. Bryant, M.D., President, in the Chair.

An Unusual Cardiac Murmur.—Dr. Walter B. James presented a medical student, aged twenty-three years, who was born in Hungary and came to this country eight years ago. His family history was negative, and with the exception of an attack of smallpox in early childhood, the patient had always enjoyed good health. There was no history of rheumatism. About a year ago, while practising auscultation upon himself, he discovered that his own heart sounds were not normal.

An examination revealed a loud murmur, heard most distinctly in the second left intercostal space, near the middle line. The murmur was neither systolic nor diastolic, but continuous, with a systolic exacerbation. It was transmitted over the entire precordial area, and could also be heard posteriorly, on the left side of the third dorsal vertebra. The heart was considerably enlarged to the left, and a little to the right side. The general health of the patient was good, but during the past year he had had some palpitation and dyspnœa, and he stated that he tired easily and was not able to study as hard as formerly.

Dr. James said that a continuous murmur of this kind could not be explained by any lesion or lesions of the heart itself: The phenomena of the heart were intermittent and could not give rise to a continuous murmur; the difficulty must lie beyond the aortic valve, in some tube or structure in which blood was always under positive pressure. The most plausible explanation he had to offer was that there was an opening between the aorta and some other blood-containing cavity in which the blood was at a lower pressure than in the aorta. The peculiar murmur in this case probably had its origin in a patent ductus Botalli. In character the murmur was somewhat similar to one which he reported about a year ago in connection with a case of aneurysm of the transverse portion of the arch of the aorta which had perforated into the superior cava.

In reply to a question, Dr. James said that no cyanosis had been present in this case. Still, with a small lesion, cyanosis would not be likely to occur. In a case of patent ductus Botalli that has been recorded, with autopsy, the patient, a woman, lived until the age of sixty. In that instance the murmur was very similar to that heard in this case.

Dr. Francis P. Kinnicutt said that, in common with Dr. James, he could not conceive of any lesion of the heart itself that could give rise to a murmur of this kind. Nevertheless it should be borne in mind that hypertrophy of either ventricle was not usually present in cases of a patent ductus arteriosus, and in the present instance the left ventricle certainly was hypertrophied. Moreover, it seemed to him that the left radial pulse was perceptibly weaker than the right. A radiograph of the case might prove of interest.

Dr. James said that his experience with radiographs of conditions in the mediastinal region had not been successful enough to make him very enthusiastic as to their value.

Dr. Beverley Robinson thought that if the condition was congenital it would probably have been discovered before now. According to his experience, the mere locality of a heart murmur was not always indicative of the seat of the lesion. In this case there was probably a mitral regurgitation in connection with some abnormal blood condition which might account for the continuous character of the murmur. The explanation given by Dr. James was certainly very plausible, but such a congenital defect would probably have been discovered earlier in life.

Dr. George L. Peabody said that, from the rather cursory examination he had made, he was inclined to believe that Dr. James's explanation of the murmur was the most satisfactory that could be given.

Dr. Hermann M. Biggs said the murmur was very widely diffused. It could be heard posteriorly on both sides, and quite distinctly over the right axillary artery. It recalled a case which came under his observation a number of years ago: the patient was a young girl with a murmur very much like this one; it was loudest in the second intercostal space and was very widely diffused, as it could be heard distinctly at the top of the patient's head and over the entire abdominal cavity. There was a little cyanosis, but not much. The murmur was supposed to be due to a patent ductus Botalli. Dr. Biggs said he could not quite understand the hypertrophy which was present in the case shown by Dr. James. It did not seem probable that a small opening between the aorta and pulmonary artery would increase to such an extent the work of the left heart.

Dr. James said that, according to all the best authorities, this hypertrophy of the left heart regularly occurred in these cases. The condition was sometimes associated with other congenital deformities, among them a narrowing of the aorta, which was given as an explanation of the cardiac hypertrophy.

The Systemic Character of Gonorrhœa: Illustrated by Five Cases of Iridochoroiditis.—Dr. Charles Stedman Bull read this paper (see page 961.)

Dr. V. P. Gibney said he rarely met with a case of typical gonorrhœal arthritis, and he could not recall such a case in recent years in which the eye symptoms were at all marked.

Dr. Biggs said he had never been able to convince himself that the salicylates were of any special value in the treatment of gonorrhœal arthritis. This affection was usually very obstinate to deal with.

Dr. Bull said the salicylates, in the cases he had reported, were not given for the arthritis, but for the iridochoroiditis, and upon the latter condition they seemed to exert a very beneficial effect. In ordinary acute iridochoroiditis of non-gonorrhœal origin the salicylates, apparently, did no good; in such cases, the iodides gave better results.

Dr. Peabody said that as the cases of iridochoroiditis reported by Dr. Bull manifested not only the urethral symptoms, but also the joint symptoms, it was quite reasonable to suppose that the gonorrhœal infection was systemic in character, and that the eye lesions could properly be ascribed to that source. In the treatment of gonorrhœal arthritis, the speaker said, he had practically seen no benefit result from the use of either the salicylates or the iodides: of the two, the former were a little more efficient.

Dr. Robert Abbe said he had seen one of the cases reported by Dr. Bull, and he could fully corroborate what had been said regarding the beneficial effects of the treatment. The eye symptoms, which were very severe, came on with great suddenness. The patient complained of great pain, and the sight was entirely lost for days together in each attack, and it seemed as though it must be permanently so. Before Dr. Bull saw the patient, ice applications were made to the eyes with very little effect. Hot applications—as hot as could be borne—were substituted by Dr. Bull, and these proved very grateful to the patient, and had a pronounced beneficial effect. Under the frequent doses of sodium salicylate a markedly beneficial effect occurred upon the eyes, while the arthritis, which existed at the same time, was apparently unaffected by the drug. The joint symptoms were best relieved by cold applications and plaster-of-paris splints.

Another point of interest in connection with the case referred to was that when the eye and joint symptoms developed the patient did not have a urethral discharge, but he had a very bad balanoposthitis. There was a free purulent discharge from underneath the foreskin and the head of the penis was covered by a serpiginous marking. On repeated search no gonococci were found in this secretion, nor were they ever found in the scanty secretion which could be expressed from the deeper urethra. Still, the gonococci were presumably the cause of the trouble. The patient gave a history of having had a urethral inflammation some months before. He made an entire recovery from his eye and joint trouble. Subsequently, while in Europe, he had another attack of iridochoroiditis, from which he also made a complete recovery.

Dr. Robinson said he had seen gonorrhœal arthritis in hospital practice, but never accompanied by inflammation of the eyes. In cases in which the salicylate of sodium is badly tolerated by the stomach, the speaker suggested that the salicylate of ammonium be substituted. The latter salt produced practically the same constitutional symptoms as the former, and was usually much better borne by the stomach.

Dr. Kinnicutt said it was interesting to learn that the salicylates proved so beneficial in the treatment of iridochoroiditis of gonorrhœal origin, whereas the joint symptoms were certainly very rebellious—if they yielded at all—to the salicylates. In his own experience, gonorrhœal arthritis was most benefited by immobilizing the affected joint and curing the urethritis. It was rather curious that the salicylates were beneficial in one affection of gonorrhœal origin, and were apparently of no value in another. Dr. Kinnicutt said he had seen one of the cases reported by Dr. Bull and at least two others in which an iridochoroiditis, together with an arthritis, occurred during the course of a specific urethritis.

Dr. Bull said that a gonorrhœal conjunctivitis could be transmitted by the hands, but not an iridochoroiditis.

Dr. James, after referring to the unusually large number of cases of gonorrhœal iridochoroiditis observed by Dr. Bull, said he thought it was quite possible that the local applications were the most potent factor in the improvement in the eye symptoms. It seemed very unlikely that any constitutional remedy could produce such marked results in one organ and not in another. The speaker said he had always found the treatment of gonorrhœal arthritis very unsatisfactory.

Dr. Bull said that four of his patients, while under his care for the eye symptoms, were having their urethritis treated locally at the same time. The speaker said he had never seen a case of gonorrhœal iridochoroiditis in which there was not a history of a preceding arthritis, and so far as he knew, there was no such case on record. A purulent conjunctivitis without gonococci was not an uncommon complication of gonorrhœa, and while the eye symptoms were apparently very severe, the patients got well without the disastrous results that almost invariably followed a true gonorrhœal conjunctivitis. Dr. Bull said he had no explanation to offer for the fact that the salicylates were apparently of no benefit in the treatment of gonorrhœal arthritis. In the cases he reported, the drug was given not for the arthritis, but for the iridochoroiditis, and experience had certainly proved its value in this condition. In iridochoroiditis of gonorrhœal origin there was invariably complete recovery with normal function of the eye, in spite of the apparently intense intraocular inflammation; this was not the case in rheumatic iridochoroiditis.

A Case of Angina Pectoris, with Autopsy.—Dr. Beverley Robinson reported this case (see page 964.)

Dr. Kinnicutt said that it was generally admitted that true angina pectoris, in the great majority of cases, was associated with disease of the coronary arteries and of the myocardium. In endeavoring, however, to explain the relation of the arterial and myocardial changes to the symptoms of angina we were met with innumerable theories, none of which was entirely satisfactory. A very good résumé of these theories was contained in Osler's monograph on "Angina Pectoris and Allied States."

Dr. Peabody said that all we could assert in regard to the general subject of angina pectoris was that the attacks were due to a temporary deprivation of the muscular structures of the heart of blood. They might be accompanied by or caused by arteriosclerosis or by arterial spasm, due to a disturbance of the nervous mechanism, and at the same time there was an irritation of the cardiac sensitive fibers and the pain started there. Dr. Peabody said it had been shown, and he had seen at autopsy, that extensive lesions of the coronary arteries might exist in some cases of angina pectoris; in others and even fatal cases the lesions were trifling—certainly no greater than those frequently found in persons past middle life who had never suffered from angina at all. In cases of artificial spasm, a condition of cardiac muscular ischæmia was produced. In some cases of angina pectoris, the cause was no doubt toxic in character, and the speaker said he had seen instances in which gout or the abuse of tobacco was undoubtedly the causative factors.

Dr. Peabody said it was interesting to note the character of the pulse during attacks of angina. In some cases it was rapid, in others slow; in some hard and bounding, in others weak. The most difficult cases he had had to treat were those in which the pulse was of low tension; that is, the old cases. He also saw cases of angina pectoris which were of peripheral origin, and some were hysterical. Those of peripheral origin were sometimes excited by very slight irritation of the left arm or the corresponding side of the chest. The speaker knew of one case in which driving with the left hand would excite an attack, and cases had occurred where even the force of the wind blowing against the chest would cause an attack of pain starting from the heart and extending down the arm. Dr. Peabody said he thought it was hardly necessary to ascribe the acute mania in Dr. Robinson's case to uræmia, as it was met with in various cardiac conditions.

Dr. Biggs mentioned a case of angina pectoris in a woman of forty in which the attack had persisted continuously for thirty-six hours when he first saw her. Its true character had not been recognized. She had a rather low tension pulse. He prescribed nitroglycerin in rapidly-increasing doses until she was taking one-fifteenth of a grain every hour, and in the course of a few hours her pain entirely disappeared. The drug was then discontinued, and within six hours her pain recurred with great severity, but it again rapidly disappeared under the administration of nitroglycerin. Another striking instance in which arterial spasm was relieved by large doses of nitroglycerin came under Dr. Biggs's observation two or three days ago. The patient was a man, fifty-three years old, whom he had seen in consultation with Dr. Stewart. There was gangrene of the left foot, extending up on its dorsal surface, and coldness and blueness to the middle of the left, and the right foot was cold and deeply cyanosed to a point well above the ankle. No pulsation could be felt in either femoral artery or the right axillary, trachial, or radial. The left radial pulse was very feeble. The man was in a stuporous condition, almost moribund. He was given nitroglycerin, the dose being rapidly increased up to one twelfth and then occasionally to one-sixth every hour, so that he took two grains or more in the course of twenty-four hours. At the end of four days an almost marvelous change had taken place in his condition. The circulation in the right leg was re-established, and in the opposite limb it was re-established down to the line of gangrene. He was clear mentally, was eating well, and in greatly improved condition. In some cases, Dr. Biggs said, small doses of nitroglycerin prove entirely effective, while in others, very large doses must be given. The question of dosage was solely a question of effect, whether we gave one-hundredth of a grain or one-fifth. Some years ago Dr. Peabody called attention to the enormous doses of this drug that could sometimes be tolerated.

Dr. Peabody said he never hesitated to administer morphine subcutaneously to patients who were suffering from chronic nephritis if the drug was indicated.

Dr. M. Allen Starr said that a patient who was suffering from mania should never be given morphine. The drug always increased the mania until such a large dose was given that it practically overcame and was dangerous to the patient.

Dr. Robinson said that in certain cases of nephritis, if the blood pressure was low and the pupils were normal or somewhat dilated, morphine might exert a more or less tonic effect upon a weakened, dilated heart, and under such conditions he did not hesitate to resort to it, when necessary. In those cases of either acute or chronic nephritis, however, in which indications of uræmia were present, when the heart was weak, irregular, or failing, when there was a low tension pulse and the pupils were contracted, morphine should not be given, unless in most exceptional cases, and then only in small, carefully-guarded doses.

The Treatment of Gastric Ulcer with Olive Oil.—Karl Walko describes excellent results attained in the treatment of this disorder by the administration of large amounts (3 to 9 ounces daily) of olive oil. This substance answers the requirements of the condition to an unusual degree, since it is a nutrient of great value, which taxes the stomach but slightly and for a very short time, while it also has a potent effect in modifying the composition of the gastric juice and in correcting constipation. Its value is increased by its unirritating nature, its ease of absorption, and the facts that it neither impedes the motor function, nor is subject to bacterial decomposition even in cases of marked dilatation. A further advantage is the inhibiting effect which fats exert on the secretion of hydrochloric acid, a property exhibited by olive oil to a very marked degree. By forming a pellicle over the ulcerated area it protects it and prevents contact with the irritating gastric secretions. It is also the softest form of nourishment after gastric hemorrhage, as it is much less apt to dislodge the clot than other foods, *e. g.* milk. The author's plan is to start giving the oil in doses of a tablespoonful, which are gradually increased to about two ounces. The mouth is rinsed with some pleasantly-flavored solution after each dose, and usually no disgust is excited. This is continued, with or without rectal feeding, to the exclusion of all other food, till the severer symptoms have subsided, a period usually of from three to six days. The addition of large doses of bismuth seems to assist the action of the oil, though the number of cases in which the combination was tried is still too small to permit generalizations. The results in all instances, of both acute and chronic ulcer, were excellent, and the action of the oil is especially characterized by its promptness of effect. On an average, the symptoms subsided within the first week, and the oil, combined with other suitable articles of diet, was kept up for a week longer. Carbohydrates can be very advantageously combined with the oil, as its presence is no hindrance to their digestion.

Book Reviews.

Manual of Gynecology. By Henry T. Byford, M.D., Professor of Gynecology and Clinical Gynecology in the College of Physicians and Surgeons of Chicago; Professor of Gynecology in the Post-Graduate Medical School of Chicago and in the Chicago Clinical School. Third revised Edition containing 363 illustrations. Philadelphia: P. Blakiston's Son & Co. 1902.

This work of 598 pages is intended primarily for the student, and is provided with marginal notes and cross references, so as to facilitate the looking up of any special topic. With the same end in view, the author has endeavored to separate the essential from the less important details by the use of small type for the latter. In the present edition the anatomy, physiology, and gynecological diagnosis and treatment have been put in the introduction, and the functional disorders at the end, or after the consideration of the diseases of which they are the symptoms. The book should prove useful to the general practitioner who makes only occasional excursions into the field of gynecology.

The Medical Record Visiting List, or Physicians' Diary for 1903. New Revised Edition. New York: William Wood & Company, 1903.

This little volume has been appearing for many years, but the reading matter of the present edition has been completely revised. Careful revision has been made of the table of average doses, all the newer drugs having been included. An obstetric chart has been added. There are various important tables, such as solutions for subcutaneous injection, emergencies, signs of death, etc. The paper, printing, and binding are all very attractive, and contribute to make this one of the most convenient of the annual visiting lists in the market.

Diseases of Infancy and Childhood. By Henry Koplik, M.D., Attending Physician to the Mount Sinai Hospital. Illustrated. New York and Philadelphia: Lea Brothers & Co., 1902.

It is impossible to take up in review all the diseases spoken of, so we will confine our criticisms to a few. The first chapter describes the ordinary method of examining infants, and ends with infant feeding. Koplik does not lay sufficient stress on the details necessary for the accurate understanding of infant feeding. This is very important for a book intended for the instruction of students and beginners in medicine. Every author must excel in some particular part. Koplik's description of the infectious diseases is certainly excellent. The association of his name with the diagnosis of measles has given him world-wide fame. Chapters VI and VII describe the diseases of the respiratory tract. The diseases of the heart and pericardium are minutely and carefully given. The author has undoubtedly weeded out the unnecessaries. The chapter on "The Nervous System and Kidneys" deserves special mention. The clinical pictures and plates in color are clearly and carefully drawn. It may be said that this book fulfils the purpose which the author had in its preparation. The dress of the book and its paper are excellent.

The International Textbook of Surgery. By American and British Authors. Edited by J. Collins Warren, M.D., L.L.D., Hon. F.R.C.S., English Professor of Surgery in Harvard Medical School, etc., and A. Pearce Gould, M.S., F.R.C.S., Surgeon to Middlesex Hospital, etc. Second Edition. Thoroughly Revised, with 461 illustrations and nine full-page plates. Vol. I, General and Operative Surgery; and with 499 illustrations and eight full-page plates. Vol. II, Regional Surgery. Philadelphia and London: W. B. Saunders & Co., 1902.

In order to keep abreast of present-day requirements, it has been found necessary to issue a new edition of the present work, and this fact alone serves to emphasize the rapidly changing and the—let us hope—advancing character of surgical science. The division of subjects in this edition is the same as in the first, but there has been extensive revision all through both volumes, and a number of new chapters have been added.

Volume I contains twenty-eight chapters, each written by a man who has devoted special attention to the particular subject, and the average excellence is very high. We commented before on the advantages of the system on which a work of this kind is produced, and the fact is made more plain in this edition. Some of the more important chapters, if we may single them out, are Chapter IV on the Surgical Pathology of the Blood, Chapter IX on the Technic of Aseptic Surgery, Chapter XVIII on Dislocations of the Hip, Chapter XXIV on Cranial Surgery, and Chapter XXVIII on the Surgery of the Lymphatic System.

Volume II is much like the corresponding volume in the former edition, and changes are chiefly in the nature of additions made necessary by surgical advances. The volume is really a cyclopedia of surgical practice, and has many advantages over the work of a single writer who attempts to cover the whole field of surgery. Such efforts are bound to be defective in some departments. Revision of this volume has been very thorough. Some of the more important chapters are Chapter VI, devoted to Thoracic Surgery; Chapter VII, on Surgery of the Breast; Chapter VIII, on Abdominal Operative Technic; Chapter XIII, on the Surgery of the Appendix; Chapter XVIII, on the Surgery of the Ureters; Chapters XXX and XXXI, on Military and Naval Surgery, and Chapter XXXIII, on Tropical Diseases Which Require Surgical Treatment, a subject which has recently assumed great importance for Americans on account of our new tropical dependencies. Both volumes are extensively and excellently illustrated, and the colored plates are the equals of any we have seen. The two volumes together form an exceedingly satisfactory cyclopedia of surgical information, and reflect credit upon the gentlemen who have edited and those who have written the chapters.

The Medical News Visiting List for 1903. Thirty Patients per week. Philadelphia and New York: Lea Brothers & Co., 1902.

In this handy little volume are 159 blank pages for records of various kinds. After the section devoted to ordinary calls, follow pages for general memoranda, obstetric engagements and practice, vaccinations, death register, addresses of patients, and cash account. There are besides, directions for keeping accounts, notes on dentition, comparative scale of weights and measures, rules for the examination of urine, tables of incompatibles, of poisons and their antidotes, a dose list, and various other items of interest.

The table of doses has unfortunately been quite carelessly prepared, and might lead one using the decimal system seriously astray, did he unthinkingly allow himself to be guided by it. For example, the decimal equivalent of 2 grains or minims is given variously as 0.1, 0.13, 0.12, and 0.15; that of 5 grains or minims runs all the way from 0.03 through 0.032, 0.3, 0.31, 0.32, 0.33, 0.35, up to 1.0—that is to say, retranslated into apothecaries' weights, from one-half a grain to fifteen grains, a rather dangerous difference if the drug happened to be morphine. In the same way, one drachm is given as the equivalent of one gram and of four grams; two fluid drachms as equal to two, four, and eight cubic centimeters, and half an ounce as six, sixteen, and thirty-two grams. The maximum dose of narceine is given as 0.3 gm., which is about ten times greater than the authorized maximum. The other less important tables seem to be accurate enough.

The Practical Medicine Series of Year Books. Under the General Editorial Charge of Gustavus P. Head, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School. Vol. XI. General Medicine. Edited by Frank Billings, M.S., M.D., Head of the Medical Department and Dean of the Faculty of Medicine of Rush Medical College, Chicago, and J. H. Salisbury, M.D., Professor of Medicine, Chicago Clinical School. Chicago: The Year Book Publishers, October, 1902.

This series is becoming better known as time passes, and bids fair to become very popular. The present volume deals entirely with some portions of internal medicine, and lays special stress upon tuberculosis, pleurisy and pneumonia, bronchitis, diseases of the pericardium, and the heart, fevers, rheumatism, kidney and blood diseases. Also gout, obesity, vessel diseases, Hodgkin's disease, meningitis, myxœdema, exophthalmic goiter, Addison's disease, osteomalacia, caisson disease, etc., are treated to a less extent. The articles from the journals of the past year have been carefully selected and condensed, and the apportioning of space has been just. Therapeutic hints have also been abundantly reproduced, as well as the more purely scientific articles on etiology, pathology, and diagnosis.

Diet and Food Considered in Relation to Strength and Power of Endurance, Training, and Athletics. By Alexander Haig, M.A., M.D., Oxon., F.R.C.P., Physician to the Metropolitan Hospital and the Royal Hospital for Children and Women. Author of "Uric Acid as a Factor in the Causation of Disease." Fourth Edition. With seven illustrations. Philadelphia: P. Blakiston's Son & Co., 1902.

The author again makes a plea for the adoption of his theories concerning uric acid, its effects and their treatment. He deals with the physiology and pathology of fatigue, and outlines a dietary such as to reduce the disturbances which are engendered by exertion, and its consequent accumulation of waste products. He espouses the claim of the vegetarians that their methods are superior to those in general use in the prosperous portions of the globe where meat is eaten freely; although he advises, as still better, the diet which he has for years prescribed. There are many valuable hints in the book, although the profession, as a rule, will consider the author's views to be those of an enthusiast.

How Can I Cure My Catarrh? By J. R. Tillinghast, Jr., M.D., Formerly Assistant Attending Physician, Roosevelt Hospital, Out-Patient Department. New York: The Contemporary Publishing Co., 1902.

The title of this little book borders so closely on the sensational that a medical man looking at it would probably be prejudiced against the work at the beginning. This is unfortunate, for Dr. Tillinghast's treatment of his theme is dignified, rational, and thoroughly professional. The book is written for the laity, and it is full of sound instruction and practical advice, but the author carefully avoids giving prescriptions or recommending drugs. Although written for non-medical persons, and in a popular style, there is nevertheless much in this little treatise that many physicians might read with profit to themselves and to their patients.

A Textbook of Pathology and Pathological Anatomy. By Dr. Hans Schmaus, Extraordinary Professor and First Assistant in the Pathological Institute, Munich. Translated from the Sixth German Edition. By A. E. Thayer, M.D., Instructor in Pathology in the Cornell University Medical College, New York. Edited with Additions by James Ewing, M.D., Professor of Pathology in the Cornell University Medical College, New York. Illustrated with 351 engravings, including 35 Colored Inset Plates. Philadelphia and New York: Lea Brothers & Co., 1902.

The work before us is an unusual one, since it is so unlike most pathological treatises of German origin in being concise and eminently practical. It is particularly adapted to undergraduate students who need instruction concerning the principles of pathology and for whom a more discursive work would serve merely as a means of confusion. In the first part on general pathology, the disorders of circulation, regressive and progressive processes, congenital anomalies and deformities, parasites, and general diseases from disturbed functions, are all well described; and we believe that the simple and interesting manner in which the facts are brought out will serve to make them fast in the minds of the reader. Many of the unusual words are carefully defined, and the philosophy of the science is at the same time brought to the front in such a way as to give a sound, broad idea of the changes to be studied in diseased tissues. The second half deals with special pathology; circulatory apparatus, spleen, lymphatics, marrow, respiratory organs, digestive and urinary organs, the nervous system, organs of locomotion, genital organs, and the skin, are all fully described. The work as a whole is beautifully illustrated, containing not only the German plates, but also some added ones, and are particularly adapted to bring out the points in the text. The printing and binding are also of the highest excellence. If one wishes a concise, interesting, and instructive work on pathology, there is no doubt that this volume will give ample satisfaction.

A Guide to the Practical Examination of Urine. For the Use of Physicians and Students. By James Tyson, Professor of Medicine in the University of Pennsylvania, and Physician to the Hospital of the University; Physician to the Philadelphia Hospital; Fellow of the College of Physicians of Philadelphia. Tenth Edition. Revised and Corrected. With a Colored Plate and Wood Engravings. Philadelphia: P. Blakiston's Son & Co., 1902.

In the preface the author states that over 25,000 copies of this work have been published, and with justice ascribes the success to inherent merit. There have been added many new paragraphs, while the old text has been corrected, supplemented, or in part omitted. The practical character of the book has been maintained, and it will be found to contain all the ordinary information which the clinician would find useful.

The Practice of Surgery. A Treatise on Surgery, for the Use of Practitioners and Students. By Henry R. Wharton, M.D., Clinical Professor of Surgery, Woman's Medical College of Pennsylvania, etc., and B. Farquhar Curtis, M.D., Professor of Clinical Surgery and Adjunct Professor of the Principles of Surgery in the University and Bellevue Medical College of New York, etc. Profusely Illustrated. Third Edition. Philadelphia and London: J. B. Lippincott Company, 1902.

The third edition of this work now before us adds another to the large number of similar works already in existence. The rapid issue of new editions of such books certainly indicates an extraordinary demand, or great advances in surgery, demanding revisions in order to include new matter. We believe that this volume has already become popular with the class for whom it is intended, and we ar pleased to say that the present edition is likely to increase this popularity. There has been a certain amount of rewriting, and the introduction of new material, but these changes are inconsiderable. The illustrations are practically the same as heretofore, and, while they serve their purpose, we may say that we have seen better. Whatever place the book has made for itself will be rendered more secure by the edition now offered.

A TEXTBOOK OF HISTOLOGY AND MICROSCOPIC ANATOMY OF THE HUMAN BODY, INCLUDING MICROSCOPIC TECHNIQUE. By Dr. LADISLAUS SZYMONOWICZ, a.ö. Professor of Histology and Embryology in the University of Lemberg. Translated and Edited by JOHN BRUCE MACCALLUM, M.D., Johns Hopkins University, Baltimore. Illustrated with 277 Engravings, Including 57 Plates in Colors and Monochrome. Philadelphia and New York: Lea Brothers & Co., 1902

IN this translation from the German edition we have not only a faithful reproduction of the original, but also some valuable additions, chiefly noticeable in the numerous engravings. These are particularly well done and instructive, while the use of key-plates to facilitate the interpretations of the colored illustrations is to be especially commended. In Part I the microscopic anatomy of cells and tissues is well handled, while the bulk of the volume in Part II treats of the histology of the organs. The concluding portion of the work gives brief and practical advice concerning the microscope, the preparation of specimens, formulæ for stains, and general directions for special microscopic technique. The book as a whole is eminently satisfactory and well adapted for teaching purposes, the text is accurate and modern, the illustrations are extremely beautiful, well selected and numerous, thus making a volume which gives positive pleasure in the handling.

A COMPEND OF HUMAN PHYSIOLOGY. Especially Adapted for the Use of Medical Students. By ALBERT P. BRUBAKER, A.M., M.D., Adjunct Professor of Physiology and Hygiene in the Jefferson Medical College; Professor of Physiology in the Pennsylvania College of Dental Surgery; Lecturer on Anatomy and Physiology in the Drexel Institute of Art, Science, and Industry; Fellow of the College of Physicians of Philadelphia. Eleventh Edition. Revised and Enlarged. With Illustrations and a Table of Physiological Constants. Philadelphia: P. Blakiston's Son & Co., 1902.

THIS little book presents the essentials of human physiology in a clear, concise manner, such as is sure to be appreciated by the student who has limited time at his disposal. The text is well divided, so that the student can readily convert the headings into questions for use in self-examination. There have been a few alterations and additions to the subject matter in the present edition, and the work can be considered thoroughly modern.

CLINICAL METHODS. By ROBERT HUTCHISON, M.D., M.R.C.P., Assistant Physician to the London Hospital and to the Hospital for Sick Children, Great Ormond Street; and Harry Rainy, M.A., F.R.C.P.Ed., F.R.S.E., University Tutor in Clinical Medicine, Royal Infirmary, Edinburgh. Fifth Edition. Chicago: W. T. Keener & Co., 1902.

THE popularity of this manual is evidenced by the demand for five editions in five years, and it is certainly well deserved. Many changes have been made in this new edition, the chief being in the chapters on the clinical examination of the blood, the nervous system, and clinical bacteriology. These have been largely rewritten and brought up to date. The methods advised for blood and bacteriological examinations are those which unite simplicity with reliability, the needs of the clinician being ever kept in mind. The descriptions are clear and concise, yet lack no essential details—indeed, one of the charms of the book is the scattering here and there of choice bits of practical information, the value of which can only be fully appreciated by those who have had to acquire this knowledge without the help of such a guide. The usefulness of the text is enhanced by the insertion of 150 illustrations and 8 colored plates, and the handy size of the volume specially commends it to the busy practitioner.

THE TREATMENT OF FRACTURES. By CHARLES L. SCUDDER, M.D., Assistant in Clinical and Operative Surgery, Harvard University Medical School, etc. Third edition, thoroughly revised, with 645 illustrations. Philadelphia and London: W. B Saunders & Co., 1902.

THIS excellent work on an important subject shows few changes in its latest edition, those changes which appear in this volume relating chiefly to the department of military and gunshot surgery of the bones. The reports of English surgeons in the South-African war offer many experiences with fractures from modern high power, small-caliber projectiles, and these form the basis of discussion in this volume. The illustrations are numerous and well executed, and those which are antiquated do not appear. The chapters devoted to the injuries of the skull and vertebræ might be singled out as being specially satisfactory. Although the work is upon treatment, the occurrence, frequency, and causation of the various kinds of fractures are sufficiently dilated upon to give a comprehensive résumé of the whole subject. This edition will, without doubt, be as favorably received as its predecessors.

DISEASES OF THE STOMACH. By J. C. HEMMETER, M.D., Professor in the Medical Department of the University of Maryland. Third enlarged and revised edition. Philadelphia: P. Blakiston's Son & Co., 1902.

THE excellent book of Hemmeter's on diseases of the stomach is now before us in its third edition. It is only about two years after the publication of the second edition. This shows the popularity of the work. The present issue contains a chapter, "Stomach Diseases Caused by Infectious Granulomata," discussing at length tuberculosis and syphilis of the stomach. With regard to diet in hyperacidity, Hemmeter adheres to a largely vegetarian diet. He has become convinced that proteids, such as beef, eggs, fish, etc., cause a stronger secretion of HCl than amylaceous foods, such as rice, farina, sago, cerealin. When the glandular layer is in a state of increased excitation it is logical to avoid proteid and albuminous food as much as possible. Hemmeter does not, however, take fully the standpoint of the vegetarian, for he allows a small quantity of easily digestible meat for dinner, and advises about 1½ liters of milk, if it agrees well. Like the former editions of this work, the present issue will be found of great usefulness to the practitioner.

LECTURES ON CHEMICAL PATHOLOGY IN ITS RELATION TO PRACTICAL MEDICINE, Delivered at the University and Bellevue Hospital Medical School, New York City, by C. A. HERTER, M.D. Philadelphia: Lea Brothers & Co., 1902.

A BRIEF review seems inadequate to place before the reader a clear idea of the nature of this valuable book. The mere enumeration of the topics touched upon, or more fully elaborated by the author, cannot convey the breadth of view and philosophical treatment of the material he has gathered for the delight and instruction of his readers. Only those who study the work can appreciate these qualities. The reviewer can only hope that his brief sketch of its contents will stimulate others to read what has given him such pleasure.

The work is divided into thirteen chapters. Of these, the first treats of the chemical defences of the organism against disease. The next two chapters deal with the three great classes of food-stuffs, carbohydrates, fats, and proteids, recalling what is known of their normal digestion, absorption, and fate in the body, and of the modifications in these processes met with in disease. The fourth and fifth chapters consider what is known respecting the value to the organism of water and the inorganic salts, iron, alcohol, organic acids, tea and coffee. Following these are chapters upon excessive fermentation and putrefaction in the digestive tract; the chemical pathology of gastric digestion of intestinal digestion, of hepatic disease, of diabetes and of starvation, undernutrition, and obesity.

An impression that the work was essentially one on a special and restricted part of chemistry, would be distinctly erroneous. It should, more properly, be classed as a study in general pathology, with a very proper emphasis upon the chemical aspects of the physiological and morbid processes dealt with. The bearing of the principles elucidated upon the practice of medicine is constantly in the mind of the author, and is lucidly set forth in these pages. These principles, as here presented, do not demand a profound knowledge of chemistry on the part of the reader. Considering its subject-matter, the work is singularly free of technicalities.

In works on pathology of recent years, so much attention has been given to morphological changes in disease, that it is a pleasure to welcome a book which so clearly treats of disease from the functional or physiological standpoint. This point of view is destined to advance medical practice in the future, and we commend this work for this reason, as well as for the large array of facts and suggestions for treatment which it contains. A very useful bibliography, with a statement of the scope and value of each reference, is appended to the chapters, and cannot fail to be most welcome to the reader seeking more detailed knowledge than could be compressed into so small and readable a volume as the one before us.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 13, 1902:

	Cases.	Deaths.
Measles	163	4
Diphtheria and croup	404	54
Scarlet fever	153	13
Smallpox	7	..
Varicella	107	..
Tuberculosis	218	129
Typhoid fever	81	16
Cerebrospinal meningitis	..	3

A New Method for Spinal Anæsthesia.—Kozlowski describes a modification of the technique of spinal cocainization, which he says robs it of all its disagreeable by-effects. Of the substitutes for cocaine that have been suggested tropacocaine gives the best results, but even this occasionally produces post-operative vomiting and headache. Inasmuch as this is the least irritating drug at our command the author endeavored to make the solution more acceptable to the meninges by modifying the solvent. This he has accomplished by dissolving the anæsthetic in the patient's own cerebrospinal fluid. His technique is as follows: The desired quantity, usually 0.05 g., of powdered tropacocaine is placed in a small graduated glass dish which has been sterilized and warmed. The needle is then inserted into the spinal canal and the cerebrospinal fluid allowed to drop into the dish. The dish is slightly shaken, which causes the powder to dissolve very readily, and as 5 grams of fluid are allowed to emerge a one-per-cent. solution is formed without the addition of any water. This is then immediately drawn up into the syringe and injected. The tropacocaine is taken from the original bottle and handled with aseptic precautions, but no sterilization of the powder is necessary. The author has performed thirty-two cases of anæsthesia in this way without the occurrence of any untoward sequels and strongly urges further investigation of the method.—*Centralblatt fur Chirurgie.*

Pathogenic Varieties of Bacillus Coli in Ice Creams.—E. Klein has isolated from certain samples of ice cream a variety of the B. coli communis, whose culture, on inoculation of minute doses into rodents, caused general hemorrhagic septicæmia, including acute gastroenteritis and peritonitis, and death within twenty-four to forty-eight hours. The microbe belongs unquestionably to the coli group. It is more motile in the hanging drop than the B. coli communis, although it possesses only one to five flagella. Like B. coli it ferments glucose and lactose, it curdles milk, produces acid and doubtful or slight indol(?). In broth culture it gives positive results in neutral red test. On potato it forms a colorless thin film. All the samples taken from different shops, but supplied by the same maker, proved to be of the same poisonous nature, and this character persisted until the maker abandoned the highly insanitary conditions prevailing on his premises, and complied with the suggestions and requirements of the medical officer. As soon as the change took place the ice cream became harmless.—*Medical Press and Circular.*

The Microbiology of the Normal Conjunctiva.—Felix Rymovitch examined the normal conjunctiva of one hundred persons with the following results: The pseudodiphtheritic bacillus was found in ninety-four, the pneumococcus in nine, the streptococcus pyogenes in five, the diplo-bacillus Morax-Axenfeld in six, the staphyloccus pyogenes aureus in six, the staphylococcus pyogenes albus in eight, and the staphylococcus albus non liquef. in seventy-nine. The relative frequence of pathogenic microbes on the normal conjunctiva renders the supposition probably that many of the sporadic cases of infectious conjunctivitis are the result of autoinfection.—*Russki Arkhiv Patologii*, etc.

The Basis for the Use of Alcohol in Therapeutics.—A. R. Cushing expresses the view that alcohol deserves a place in therapeutics as a narcotic, and to a less extent as a stomachic, and in certain conditions as a food. He would not disguise the fact that it has drawbacks, like every other drug, but would plead that we must not allow ourselves to be guided entirely by consideration of any one of its properties, but must estimate in each case whether the sum total of its effects, good and evil, will benefit the condition.—*Quarterly Journal of Inebriety.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending December 13, 1902:

ON SOME OF MY PRINCIPLES IN ORTHOPEDIC SURGERY.*

By PROF. ADOLF LORENZ,
VIENNA.

I consider it a great honor to be allowed to appear before you, and I know of no better way to show my gratitude than by asking your permission to explain to you some of my principles which hitherto have ruled my orthopedic work.

I hope to meet your approval at least regarding some of these principles; as to others, which may rouse your opposition for the moment, I hope you will find them worthy of your objective trial. Even if these principles do prove to be different from yours, certainly we, who are on both sides of the Atlantic, which divides the places of our work, completely agree on the same aim, that is, to help our patients in the best way. As to my methods, I can recommend them as both safe and successful to the patient. In saying this, I touch upon my leading principle, that is, curing my patients without any danger of loss of life. Luckily, deformities seldom offer what we call *indicatio vitalis*, therefore when we operate on deformities we should never arouse even the possibility of putting the life of our patient in danger. Following this principle, I generally prefer bloodless operations to the bloody ones. In many cases the results are the same, but usually those of the bloodless ones are better. As long as the bones are elastic enough, I prefer osteoclasis to osteotomy; this latter operation is exclusively reserved for adolescents and adults. In hip deformities I prefer bloodless corrections to osteotomy, as long as even the slightest motility of the joint is present; only in cases of complete bony ankylosis do I operate with the chisel.

All cases of knee contracture I correct by the intraarticular modelling redressement, as long as even the slightest motility can be found. Only cases of complete bony ankylosis of the knee-joint, which are rarer than is usually believed, are reserved for the bloody operation.

In all deformities of the foot, both paralytic and congenital, I rely exclusively upon my modelling redressement of the foot, and from a thousand-fold experience I can assure you that the results are generally beyond expectation. In my opinion the wedge-shaped excision of the bones of the foot, newly recommended by the French, is nothing more than a deplorable mutilation of the foot. The results of the modelling redressement of club-foot have been preferred by many others, and I am happy to say that at least in Germany this method is predominant

On the whole, I dare say that I prefer bloodless operations to the bloody ones as long as any possibility exists of securing the result in this way. According to this principle, I cannot sympathize with the total extirpation of the sternocleidomastoideus in wry-neck. After my experiences, the subcutaneous myotomy of this muscle in connection with the modelling redressement of the cervical skoliosis is perfectly sufficient to cure the caput obstipum thoroughly and without leaving a scar. In this realm I go even further, as the congenital caput obstipum in children can be cured even without tenotomy, only by myorrhexis of the sternocleidomastoid muscle, and the results obtained by this method are the most perfect ones, from a cosmetical standpoint. The ruptured muscle regains its normal length, as well as its normal elasticity to such a degree as to allow the head to move freely to the opposite side. Besides this, the ruptured muscle retains a normal prominence with its partner, restoring the normal configuration of the neck, in this way avoiding the known applanation of the operated side, which usually occurs after open or subcutaneous myotomy.

Following this principle, you will share many advantages with your patient. The latter readily consents to be operated upon, as he runs no risk to life, and as for yourself, you will feel quite easy about him.

Another principle which I have always followed is the so-called "central correction" of deformities, which means that every deformity should be corrected in the vertex of its angle. If you should prefer to correct a deformity in one of the sides of the angle, even near the vertex, the deformity itself would remain, and instead of a correction, you would have only a compensation for the deformity. This compensation implies some shortening of the side of the angle, that means of the leg, which shortening should be avoided under all circumstances. This principle is very important with regard to the contractures of the hip-joint. It is obvious that subtrochanteric osteotomy contradicts the above-mentioned principle. By correcting or compensating the deformity, you shorten the leg. Agreeing with the principle of central correction, I always do central, that is, pelvo-trochanteric, osteotomy. Having performed this operation, correction is very easy without causing any further shortening of the leg. I object even to oblique subtrochanteric osteotomy, although it avoids shortening by a complicated and difficult extension after treatment, by which the patient is confined for some weeks to his bed, instead of being able to get up a few days after the operation.

Following the principle of central correction, you will also object to supracondylic osteotomy or osteoclasis in correcting the contractures of the knee-joint. In preferring central, that is, intraarticular, correction, you will avoid shortening the limb. In correcting genu valgum the principle of central, that is to say, infraarticular, correction cannot be thoroughly attended to, because—except in cases of young children—a loose knee is to be feared, and, besides, the treatment takes too much time. In genu valgum supracondyloid osteotomy is still the predominant method, because of its general reliability, but, beyond doubt, epiphysiolysis on the lower end of the femur allows better correction of the deformity, being a more central method than the supracondylic osteotomy. Unfortunately, the method of epiphysiolysis is available only in children from five to sixteen years.

---

*Address delivered before the Orthopedic Section of the New York Academy of Medicine, December 19, 1902.

Another important principle of modern orthopedic surgery is that of absolutely saving the bones by dividing the soft parts as far as circumstances may demand it. This conservatism toward the bones and this radicalism against the soft parts (just the inversion of a principle of former times) condemns all cuneiform osteotomies and resections *en bloc*, of the bones, and makes it a rule to correct deformities by simple linear osteotomy, sacrificing the soft parts as far as may be desirable. Indeed, it is very easy to correct every hip deformity of whatever degree by simple linear (pelvitrochanteric) or central osteotomy, after having thoroughly divided the adductors and the subspinal soft parts. It is of no importance whether you divide them in open wound or subcutaneously, you must only divide them thoroughly. The wedge-shaped excisions of bones in correcting knee contractures are likewise to be avoided, or, at least, to be reduced to a minimum by regardless radicalism against the soft parts in the fossa poplitea. As to the excisions of bones in the treatment of club-foot, I have mentioned above that I abhor them.

The principle to correct deformities only by simple linear osteotomy is even available in those most difficult cases of bow-legs with anterior convexity of the bones. In such cases I apply one or two linear osteotomies to the center of the deformity, then I add achillotenotomy and sharp screw extension above the ankles until correction is made.

Another principle of common interest refers to the treatment of tuberculous diseases of the joints in children, and to the treatment of deformed paralytic limbs. I must avoid discussing the question whether operative or conservative treatment should be carried on in these cases. My standpoint on this question is rather one of expectancy. But I do not hesitate to declare that up to now I have never made a resection of a tuberculous joint in children, and that the results of conservative treatment seem to me far better than those of operative treatment. Nevertheless I am far from denying the necessity of operating in some special cases, particularly in common hospital practice. However, the principle of which I will speak refers to the question whether or not mechanical treatment should be carried on in a way to exclude all functional work of the limb during the whole treatment. Observation of nature let alone seems to me to give the answer to this question. If we contemplate a case of hip disease never interfered with by any treatment at all, we learn, in many cases, that nature, unhelped by our mechanical means, needs no more time to cure the disease than we do. After some two or three years all may be over. During this time the sick child may have been confined to bed with great pains in the hip joint for some months only. During the rest of the time they walk about without the help of crutches as well as they can, using the limb according to the actual state of sensitiveness. After all the disease heals without any suppuration even, and, finally, we see these children come to us to get rid of their deformity. We find a contractured limb, but fit for function even under the unfavorable mechanical conditions of the deformity. We find the bones solid and the soft parts not so much wasted as we expected; and last, but not least, we find that the growth of the limb has not been much interfered with by the disease. These cases are the best objects for operative treatment because the good state of the legs very soon enables them to profit by the correction of the deformity. If we compare one of these cases of natural healing to the results of our mechanical treatment, which may have begun at the first sign of the disease, we will find that we have scarcely shortened the course of the disease. We accomplish a diminution or suppression of pain, and may keep the limb in a tolerably good position. But surely we shall find the leg in a wasted condition, the muscles being flabby, the bones lacking solidity, and quite unable to support the weight of the body, although pains have long since disappeared. Probably we shall find, besides, that the growth of the leg has been much interfered with by the disease. There can be no doubt that this deplorable condition of the limb is due to the fact that both by suspension and fixation by our mechanical means the leg has been totally excluded for many years from every function of movement and weight carrying. From this consideration is derived my principle to exclude the diseased limb no longer from a measured function if severe pains will not forbid it. I never allow any movement of the diseased joint, but I suspend the weight only as long as the pains demand it, always taking proper care to procure slight abduction of the leg. As soon as the pains allow it, I begin to attend to the muscles by massage. Of the movements, only active and passive abductions are made in the later after-treatment to prevent the tendency to abduction.

My final aim is to procure a solid ankylosis of the hip-joint, combined with good position of the leg, experience having taught me that great mobility and bad function with lack of any endurance are common allies. I would welcome, with greatest enthusiasm, a method which would procure a true bony ankylosis of the diseased hip-joint, bony ankylosis of the hip and good position of the leg being the condition for the best result from both a cosmetical and a functional point of view.

As you may have seen by what I have said, I make little of the permanent extension. I consider extension only a matter of fixation; direct and indirect fixation together naturally give a greater degree of surety. I have said that every articulation attacked by chronic disease should not be prevented from function any longer than is absolutely necessary. In saying so I turn against the method of treatment generally used in Germany, which makes the patients wear their pressure-relieving and fixing apparatus so long that they become slaves to them. This same principle I emphasize using in the treatment of paralytic deformities. I am convinced we render no great service to our patients by making them wholly dependent upon their apparatus; the limbs atrophy by exaggerated use of apparatus to such a degree that they become useless for any function. It is my practice to correct thoroughly the paralytic deformities by modelling redressement, in case of need combining the transplantations of the tendons, and to fortify the rest of the muscles by massage and exercises in order to secure the obtained correction. For the rest, the patients must be accustomed to make use of their legs as much as possible without apparatus, or by assistance of the simplest one. Generally, a flannel bandage or laced boot will give the necessary support. In any case I take care to secure the corrected position during the night by means of a simple apparatus. I think that enclosing the leg in a steel support is to be avoided, as by so doing the leg will be excluded from any function. On the contrary, I try to make the leg independent of mechanical appliances as far as possible. Only in the treatment of total paralysis, which fortunately occurs rather seldom, the permanent use of mechanical support is indispensable. In the treatment of skoliosis I am wholly against the exclusive application of mechanical supports, especially against those which are worn day and night. I restrict the use of corsets to special cases which evidently want a support. Besides I take special care of the muscles of the back by exercising them, and endorse the necessity of forcible antiskoliotic gymnastics.

I think it is unnecessary to follow these principles in detail, and I hope you will not object to my endeavoring to solve the problems of orthopedic surgery by operative treatment, and, if possible, by a bloodless one, and to restrain and simplify orthopedic appliances.

If the surgical task has been thoroughly solved, orthopedic appliances, if necessary, may be of very simple construction, so that special mechanical ateliers may be considered superfluous. If orthopedic surgery conceives and carries out its themes in such a way, then it will be possible to indulge in orthopedic surgery at every surgical station, even if great mechanical means may not be at hand. Then orthopedic surgery will not deny its democratic character, which it must have to be able to communicate its progress and improvements to even the poorest children who may be in want of relief.

WHAT CAN BE DONE TO PREVENT THE SPREAD OF SYPHILIS.

By E. HARRISON GRIFFIN, M.D.
NEW YORK.

LECTURER ON DISEASES OF THE NOSE AND THROAT IN THE NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; ATTENDING SURGEON TO THE THROAT AND NOSE CLASS OF THE OUTDOOR POOR DEPARTMENT OF BELLEVUE HOSPITAL.

It is not my intention in this article to enter upon the question of whether prostitution should be legalized or not, but to show how, when syphilitic cases come under our observation, tact exercised can, in part, curtail the spread of this disease and keep it within bounds.

In an active service of twenty years in the Dispensary of the Nose and Throat of the Outdoor Poor, I have seen syphilis, in all its forms, from the primary lesion in the home locality to the chancre situated upon the nose, the lip, the scalp, the tongue, the tonsil, the gums, the hand, the ear, and the finger. I have found it ensconced in the old man of threescore years and ten, and in the infant of nine months.

Some years ago, in looking over the throat and nose cases that had come under my care, I found that syphilis, in some form, as the initial lesion, the mucous patch, the deep ulcer, or the necrosed bone, made its appearance in every thirteenth case. The number had an ominous significance.

Syphilis is not a disease of class or of age. It is found unstinted among the rich and generous among the poor. Among children I do not think that it is a rare disease. I have seen the initial lesion in a number of children, when the diagnosis had been everything but the proper one. Syphilis is not confined to the recognized roué, but is again and again found inoculated in the system of the innocent who have accidentally come in contact with this virus.

I had a young lady of the most estimable character call. She applied for a sore on the under portion of her upper lip. The location was unique. This woman was inoculated from an orange. She was accustomed to buy one from an Italian every morning on her way to school. Later on she would suck the juice out at the end. The location of this chancre corresponded to where the lip would be used in this operation. At my request, she watched the Italian, who would expectorate on his oranges and then use a rag to give the fruit a polish.

I have treated men at the clinic whose mouths were filled with mucous patches, who sold toys on the street that had to be blown up by mouth. These they would sell to children.

I had one case in which a man sold a piece of rubber that made a noise like a bird. This man was afflicted with syphilis, was warned by me, and, in fact, threatened, still he plied his business in front of schools, sold his rubber whistles, after he had tried them himself to see that they worked properly.

These men should have their licenses countersigned by the Health Board before they are allowed to sell or disperse any goods where the mouth is used as a means of displaying them. This inspection should be done at certain intervals. It is a simple suggestion, but it is a most effective one.

The fruit vender caught expectorating on his fruit (it is a common occurrence, and the more expensive the fruit, the more this luster) should be fined at least equally with the transgressor who expectorates upon the floor of a car. Notwithstanding the fact that he uses his spittle to enhance the charm of his goods.

Cigarmakers have been under my care for syphilis of the throat. They have brought me cigars they made (which I did not smoke), showed me how they moistened their fingers by their spittle to give the cigar a certain twist. The majority of cigarmakers use water from a basin, still this manner of using the mouth is not obsolete.

Syphilis is not a venereal disease, properly speaking, nothing like so much so as gonorrhœa. Syphilis does not need contact with the opposite sex to have it ingrafted into one's constitution. I have seen cases of the initial lesion of the buccal cavity, or its vicinity, caught by drinking from a tin pail. One case inoculated three other children in the same family. The cases I saw I treated, but how many more were inoculated by these children, whom I did not see, I cannot say. I have had cases in which the contagion was caught from rouge applied to the lip, the former user having had syphilis.

I saw a case of chancre of the scalp in which the man contracted his contagion by being bitten by his opponent in a drunken fight. This was substantiated by a well-marked syphilitic eruption following the sore. A chancre of the wrist, I have also seen, caught by the patient being bitten by a syphilitic fighter.

These four illustrations will show how easily one can be inoculated innocently. These facts should be taught to the laity as thoroughly as the germ theory of consumption is taught.

This knowledge would help the laity to protect themselves and the children who are the innocent sufferers of a guilty father or mother.

It is interesting to stand near a drinking fountain in a hospital or dispensary. The drinking vessel that is used is invariably a tin cup with its edges twisted upon a wire—a hot-house bed for the collection of syphilitic virus.

Persons whose mouths are covered with syphilitic infection go to these cups and take a drink, and by so doing charge the cups with many syphilitic germs. The next comer may be the one to receive his inoculation.

This is no fancy picture; it is one that is enacted every day in New York—a city which boasts of its medical colleges and its excellent Board of Health. The question comes up, why does this exist? For the simple reason it is nobody's business to see that a glass cup with smooth edges is supplied, instead of the tin one—a greater breeder and disperser of germs was never manufactured.

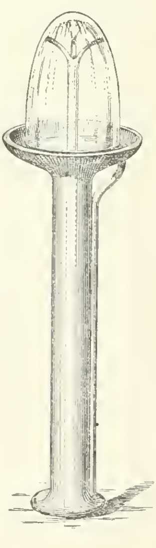
To understand how syphilis is spread, you must watch the syphilitic and the solution is easy.

A cup like the drawing below should be ordered by the Board of Health, to be used in all public places. It should be fashioned very much like the one used in the trains, with a cone bottom, so it can not be placed downward, and a round, smooth lip like the old-fashioned coffee cup without a handle. This round lip renders it easily cleaned and less liable to harbor germs.

If a water-attachment like the above cut were made, the glass could be placed on the raised pillar, and the small jet of water constantly running would bathe the vessel, so it would be invariably antiseptic the lower part rests in a trough so this part is also bathed.

Syphilis of the buccal cavity is a common disease. I have seen over seventy to eighty primary chancres of this region. The reason that these cases are thought uncommon is because the lesion is not recognized.

Syphilitics have a fondness for picking their lips and passing their fingers into their mouths on exploring expeditions. When their hands are well covered with their saliva, I have seen them open the dispensary door, depositing this moist saliva, reeking with syphilitic germs, upon the door-knob. The next comer with an abrasion becomes the innocent possessor of a lifelong affliction.



This I have seen so often that I never think of opening my dispensary door after I have washed my hands preparatory to leaving, unless I use some cloth to cover the knob.

The knob could be done away with entirely, and the door could be opened by means of a spring manipulated by the foot.

Remember, dispensaries are places for the sick of all classes and of all diseases, thus, when we strive to cure we should strive to prevent one patient inoculating another with a disease more fearful than the one he had at first.

In Central Park there is a number of urinals situated behind little iron screens. The urinal is patronized by the male of all ages, from the boy of six to the old man of eighty years.

No allowance is made for the small boy being shorter than his male companion. Thus the man urinates, and is able to flow his stream downward without touching the edge of the urinal. When the small boy comes along, I have seen him rest his part on the edge of the urinal, the place that only a few minutes before had received the shakings from a syphilitic penis. This can be easily remedied by having the trough on the floor, and doing away entirely with the elevation.

The urinal of the present pattern is a most excellent disperser of the syphilitic germ. All syphilitics should be taught to use a cloth that they can burn. If the syphilitic is in such circumstances that he can afford to burn his handkerchief and keep himself supplied with fresh linen, there is no objection to the handkerchief; but when this article of apparel is used it generally finds its way to the wash, where it becomes a means of spreading the contagion to whomsoever washes the linen.

A small piece of cheese-cloth of a fine texture and closely woven is inexpensive, easily bought, and easily destroyed, and does away with all means of infection. This has been urged in tuberculous cases. If it is necessary in these cases, it is imperative in syphilis. Syphilis caught while in the performance of their handicraft is common among washerwomen. I have had a number of cases in which the disease was caught in this manner. When the initial lesion is present the patient should be warned to keep a cloth attached to his shirt, so that the shirt will not become a means of dispersing the poison. If it becomes soiled it should be burnt, not washed.

If I had not seen so many cases and known of more infected after this manner, I would not dwell upon this manner of spreading syphilis among the innocent. If syphilis must be caught, let it be where two guilty ones are the transgressors, and not where a woman strives to earn a livelihood in a legitimate occupation.

The washing of spittoons that are used in public places should be done with care after their contents have been disinfected. I mention this, as I have often seen patients spit in a cuspidor in the hospital, and have seen a scrubwoman put her hand in the cuspidor directly afterward to clean it. I do not wonder that there is so much syphilis—I only wonder that there is so little—with the inadequate means that are used to prevent its spread.

To curtail the spread of this disease, the public must be educated, and educated thoroughly, the same as they are to-day in regard to tuberculosis. Then syphilis can be brought within bounds, and in coming generations the disease would be a rarity, and not one, like to-day, found grafted upon some of the best families of the city.

When a nurse is hired to perform her duties in a sick room, an inspection of her mouth, if she is seen picking it, would be serviceable.

I had a lady, a nurse, brought to my office for a sore throat. I watched her before I made an examination of her mouth, and was edified to see her pick her lips, run her fingers again and again into her mouth, and then wipe them upon her cheek. She was well-dressed, her lip was infected by a primary chancre, then in full bloom. Large buboes were on the side of her neck, and a syphilitic eruption covered her body. This lady had two hours before left a patient whom she was nursing, and had been nursing for two weeks, during which time, undoubtedly, she had picked her chancre the same as when I saw her. She was a nurse, but, I must add, not a professional nurse; but nursing was her occupation.

I had a midwife come to the hospital with a chancre of the tongue. This woman performed her duties, and was surprised to know that the disease was contagious.

In the International Conference for the Prophylaxis of Syphilis and Venereal Diseases, in Brussels, it was suggested that sanitary supervision should be exercised over all the subjects of venereal diseases who are notified by the doctors or the police as being dangerous to the public health. This supervision should be carried out in the following manner:

The gravity of venereal diseases and the necessity of continence should be impressed upon the patient, and, in the event of the instructions being disregarded, the police should make a legal complaint. This part would fit the above and the following:

A man, aged about twenty-six years, well dressed, and of some means, applied, some years ago, at my clinic complaining of a sore throat. His lips, his tongue, and his palate were a nest of mucous patches. This man was a heavy drinker; he was also addicted to chloral and morphine, a thorough degenerate. I warned him of the nature of his trouble, and explained to him the means he must employ to prevent its spread. He smiled. I then turned and accused him of kissing his female friends. He acknowledged, candidly, that he had kissed everybody—his sisters, his mother, and any lady he had a chance. Here is a case of a man not insane enough for a sanatorium, but not sane enough to be allowed at large. A syphilitic with the contagion at its height—a drunkard, a morphine habituate, and a chloral fiend—a weird combination.

All chancres and mucous patches when first found, and dignosed positively as such, should be destroyed by some caustic, as a sanitary measure, to prevent, in part, its dispersement.

I have had a case in which the husband contracted chancre of the lip; this was repeatedly cauterized. His wife was not infected until eight months afterward, when she became infected with a chancre of the lip, from a mucous patch brought out on her husband's lip by smoking a cigarette against my instructions. I believe, and I believe thoroughly, more syphilis is caught and dispersed by the mucous patch than from the primary chancre.

The eruption accompanying a chancre is nature's red flag, a signal of warning to beware, but the mucous patch, equally as contagious, is only a silent exponent, and seldom accompanied by a danger signal, except upon a close inspection.

The importance of the mucous patch and its ability to spread syphilis, should be taught to the unsophisticated, and they should know that this means of contagion is, as I have said before, more common.

A chancre will heal without any medication; the skin eruption will fade and pass away without any drugs, but the mucous patch of the buccal cavity, the vagina, or the penis, is a head-stone of a disease that may have passed partly away, but has not departed, and is ready to be born again.

Prostitution in New York City will never be legalized until politics can be changed. But prostitution and syphilis can be restricted. To raid one house and scatter its inmates into new surroundings is like detroying a house infected with the plague, and allowing its infected members to inoculate a new quarter. Prostitution should be confined, by an unwritten law, to one section of the city, and those found plying their trade outside of this quarter should be made amenable to the law. An infection of a prostitute by a male should render the latter also punishable. The scope of the subject is so wide that it cannot be digested in these few pages. Palpable suggestions can only be hinted at.

All women arrested on the streets as known prostitutes should be examined in the morning before they are brought to the court. If they are infected with syphilis they should be given a card, after their name and address have been taken, and they should be compelled to go to a physician, private or otherwise, and they should show a card from the same physician, showing that they are under medical care. This report can be made to the police surgeon. If they do not make this report they should be liable to a fine.

Years ago, in my early practice, I treated, at my office, a young woman who was in a house of prostitution. Her mouth and other parts were covered with mucous patches. I warned her to give up her business till the sores had healed, and to tell the madam of her condition. She said if she told the madam of her condition she would turn her out into the streets, and, as she was without means or a home to go to, this girl had to dispense syphilis to her male friends, for her breakfast, her dinner, and her lunch.

The law is establishing homes and hospitals for the consumptives, but allowing a disease more virulent, just as prevalent, but overlooked because it has the immodest name of a venereal disease. It is like cleaning a street at one end of a block and dumping the refuse at the other.

Why should we, as physicians, be compelled to report our cases of typhoid fever, smallpox, diphtheria, and kindred diseases, and to ignore reporting syphilis to the Board of Health? All cases of syphilis should be reported, especially when its possessor is liable to spread the contagion after he or she has been warned of the nature of the malady, and still persists in scattering its poison. These cases should be placed under surveillance the same as one infected with diphtheria.

The women of the town are not the only transgressors; if they had not met some man with this disease they would not be syphilitics. They have to receive the poison before they can transplant it.

It is a notion among some people that if they with a chancre have connection with one of the opposite sex, they can give the disease to the opposite party, and thus rid themselves of the poison. I have been asked again and again if this was true. Still we go on enlightening the public in regard to tuberculosis, but blind them in regard to a greater evil. Many patients are afraid to tell their family practitioner of their error, and fall into the hands of some advertising quack.

I treated a case years ago of a man who applied to me for a gonorrhœa which he had had for three weeks. This man had been under treatment daily, in the hands of a well-known newspaper advertiser who had seen him the day before I had seen him, and he had received a deep urethral injection from his hands. The diagnosis had been gonorrhœa, pure and simple. An examination of his penis showed a large chancre on its corona. This had been entirely overlooked by the quack. An eruption followed, with the usual throat lesion. Here is a case in which the patient might have married after his gonorrhœa had been cured and have inoculated a healthy woman with syphilis.

In this city we are not dealing, as in France, with a French population, or, as in England, with an English population, but our people, who apply to charities for help, are of a polyglot nationality.

We have the English, the Germans, the French, the Italians, the Russians, the Bohemians, and, in fact, every nationality under the sun, making up the great population of the city of New York. Some of these people are educated, some are grossly ignorant, and these are in the majority. These are the people who spread syphilis. These are the people who should be taught the importance of the contagious nature of syphilis. A practice of twenty years or more among this class in a dispensary gives a physician many valuable points in regard to their understanding.

Again and again I have treated a case at the hospital, warned the man not to marry under three years, and in the space of a few months I have had him bring his wife, to whom he had been married for only a few weeks, infected with syphilis. If these cases were taught thoroughly, and they can be taught, and be made to understand that syphilis is a contagious disease from the mucous patch if the instruction be done systematically.

I would suggest that each and every patient that applies to a hospital or dispensary be given a card, furnished by the Board of Health, in various languages, with the salient points in regard to how syphilis is spread: Something, as follows, might answer. It is a simple matter, but it would help, and help greatly, to curtail this rapidly-spreading disease, and to bring it within a circle where it could be scientifically dealt with:

You are affected with syphilis and will spread this disease if you do not follow out the following instructions:

1. You should use pieces of rags, not handkerchiefs, for your mouth (fine cheese-cloth, cut into squares, will answer the purpose); the cloths should be burnt, not washed.

2. You should use the cloth at the table, and not a table napkin, as the washerwoman is liable to infection in washing these napkins.

3. Under no circumstances should you kiss anyone, as the secretion from your sore mouth will spread the contagion.

4. This contagion is in your blood, and is liable to break out if you stop medicine, which must be persisted in for three years.

5. All alcoholic drinks are prohibited if you desire to be cured.

6. Smoking renders the lips liable to patches, which will convey the poison of syphilis.

7. Any sore on your mouth is dangerous; apply immediately for treatment.

8. Do not drink from any cup in a public place unless you wash it out afterward, as any virus from your mouth dispersed on the cup will spread the disease, and it may be to your own mother or father.

9. You must not marry for three years. All symptoms of your disease may have waned, but the disease is still in your blood. Marriage means that you will infect the woman you make your wife, and if she has any children they will inherit your disease. The disease in your children will be harder to cure than your own.

10. Apply regularly for treatment and your medicine once a week. The department furnishes enough medicine to every applicant for one week, but not longer, as it is imperative that you call, so the medicine can be changed if necessary.

I have made mention here in regard to medicine for one week, because medicine is not furnished in this class of cases for this time. These receive only enough for two or three days. Thus patients who are anxious to continue treatment are actually prohibited by law from being cured, because the dispensary will dispense only enough for a three days' treatment.

Many of the patients cannot call more than once a week for their medicine, and after the first four weeks of this disease it is not necessary that they be seen oftener, if the treatment has been conscientiously followed out. These people are too poor to buy medicine. Yet the law of the dispensaries demand that they leave their employment, and possibly lose their situations, because not enough medicine is given to carry them over the stated period.

Let us try to stamp out this disease by giving the patient enough ammunition to carry on the battle. Patients affected with syphilis should be examined regularly every one to two weeks. Their mouths should be examined carefully for a specific lesion. The buccal cavity will show signs of syphilis long after the skin lesions have disappeared.

These lesions are not painful, as in tuberculous affection. I have seen the entire larynx involved in syphilitic ulceration, and the patient did not know that he had a sore throat. The absence of pain when these lesions are present, whether they be the mucous patch, the superficial ulceration, or the deep ulceration, is the rule, not the exception.

This summer I met a patient of mine on Broadway. He had been West for a year, playing in one of the Western States. He had played juvenile parts, and his wife had been the leading lady of a company. The two I had known for years. They had a couple of children, and were as devoted as a couple could be. His wife contracted syphilis from kissing one of the company, the party playing the lover on the stage. This lady was treated for smallpox, and almost every disease except the right one. It was over six months before a correct diagnosis was made. Her husband contracted syphilis from her three months afterward. He told me this history on Broadway, and said that his throat had been sore, but was then splendid. He called at my office the next day. I found the throats of both husband and wife one mass of mucous patches, and in a most fertile condition to spread the contagion in all quarters. This couple did not know that their throats were sore, and were about leaving the city to play a summer engagement and most likely to spread the poison, in their turn, among some more actors and actresses.

This is not wilful inoculation—it is simply the lack of knowledge, or rather the lack of education of the masses. Take up the subject and teach it as tuberculosis is taught, and these cases would not occur.

Tact must often be used when the question comes up, whether we shall notify the parents, especially if the patient is a young girl.

A young girl, fourteen years of age, was brought to the clinic complaining of a sore throat. She had a follicular tonsillitis; but there were sores present on the tongue that suggested syphilis. The patient was accompanied by her mother. I sent her into a little room and asked her to remove her waist. When I entered the room the mother told me that her daughter would not remove her things till she, the mother, left the room. I demurred at first, but the girl was positive in her demands that the mother must leave the room. After the parent had left, the girl willingly removed her attire and showed her body covered from head to foot with a syphilitic eruption.

She asked me not to tell her mother. The girl was a Catholic, but had not been to confession for three years. I made her promise to go that afternoon, which she did.

The girl married three years afterward, and turned out a most excellent wife. If I had told her mother, the girl would have received a beating, to use the mother's expression, and been turned out into the streets, and in two weeks a full-fledged prostitute of fourteen would have been on the town, and one most capable of spreading the disease.

Diplomacy must often be exercised in questioning syphilitics. A young woman, aged nineteen, applied for treatment of a sore throat. An examination showed an extensive ulceration, involving the pharynx from one pillar of the fauces to the other. I placed her under treatment and asked to see her husband. He came down the following day. I asked him when he had had his chancre. He denied ever having one, never had a gonorrhœa, or even a skin eruption. I told him that it was no use denying that he had had syphilis, as his wife was infected. He told me that he had been married only two weeks; his wife was a widow at nineteen when he married her. I always ask now if my patients have been previously married.

I had a case of syphilis sent to the clinic in which the disease had been diagnosed as diphtheria, and the patient was about to be sent to the Willard Parker Hospital for treatment. This mistake was made by the physician of one of our large hospitals on the west side of New York City after the same diagnosis had been made in a large hospital on the East Side. The correct diagnosis was a deep tertiary syphilitic ulcer of the pharynx, which granulated rapidly under the iodides. The papers were made out for this patient to go to the Willard Parker Hospital, and I saw him only by accident.

I had another case sent to me by a prominent surgeon, with a note which stated that if I advised an operation he (the surgeon) would place the case under my hands for the knife. I sent this patient back in two weeks with the condition healed under the iodide. The case had been mistaken for one of cancer.

Another case of mucous patches was brought to my office by a well-known specialist on skin diseases, who makes a specialty of syphilis. He brought the case of mucous patches to me as one of mycosis.

If there is a difference between a rat and a rhinoceros, there is a difference between a mucous patch and a mycosis of the buccal cavity.

I heard one eminent dermatologist state: "Gentlemen, there is absolutely no mistaking the diagnosis in this case (the patient had an ulceration of the dorsum of the tongue). This is a plain case of epithelioma; the tongue should be operated upon immediately." Two weeks afterward, under large doses of iodide, the ulcer was almost completely healed.

A physician brought his niece to me this year. She had been under treatment for her throat for several months. Numerous physicians had been seen and various treatments had been prescribed. She grew worse. As a last resort she was sent to Florida, where she still continued to fail. She was brought North to consult me. I diagnosed syphilis, from a large ulceration that I found on the pharynx. Three weeks under the iodides healed the sore. This lady had contracted a chancre of the finger while washing one of her uncle's operating knives, which he had previously used upon a syphilitic. My diagnosis recalled the fact, although up to this date syphilis was not suspected. Are we blind, or can we not see facts when they are presented?

One of my old patients with tertiary syphilis applied to a large hospital that was near her residence. The physician examined her throat, referred the case to the chest room, where the physician reported the case to the Board of Health. The inspector called at her house and warned her that she had tuberculosis; she must be careful where she spat. The patient gained twenty pounds in six weeks under the iodide of potassium. It was a case of a deep tertiary ulceration, pure and simple, involving the epiglottis and ventricular bands. The cough and the loss of voice misled the physician.

Cases of primary chancre of the lip have been sent to me as cases of mumps. These mistakes lead a practitioner to only one conclusion, and that is that syphilis has not been taught thoroughly in our medical colleges.

A patient is brought before the class, wrapped up in a blanket, which he throws aside, and his skin is shown dotted or flushed with a syphilitic eruption. The eruption is commented upon. The head is shown to demonstrate the alopecia, but the throat symptoms are ignored or passed over so lightly that syphilis has been called a skin disease; a more mistaken name was never given.

If it can be classed, I use the word "can," because syphilis is, like Joseph's coat, of many colors; it belongs, more properly, under the diseases of the mucous membrane, and the part that becomes the alpha and omega of syphilis is the buccal cavity.

Here we should look for our mucous patches, our deep ulcerations, the open sesame of our diagnosis. Syphilis is taught more thoroughly to-day in our colleges. Section teaching has brought this about. A professor can describe the syphilitic lesions of the buccal cavity for over an hour, but ten minutes in a clinic, where the proper light can be used, will implant on the brain of the medical student more thoroughly, more concisely, and more vividly these lesions, when he can see them himself, than ten years of a didactic course.

Syphilis travels in a circle; man infects the prostitute, the prostitute infects the man. Thus syphilis, like the boomerang, comes back to its starting point.

The education of the masses in regard to syphilis, and a conscientious teaching of this disease to the laity, would, in part, prevent the spread of a disease that infects all classes of society, all professions, and all workers. If the disease would stop here and kill only those it first infected, less harm would be done. It goes traveling on, in the majorty of cases, to the children of the syphilitic who, if they, in turn, procreate, give birth to a child so fragile, so delicate, so frail, that a few years will suffice to wipe this offspring off the face of the globe, and the child will be buried as having died of inanition.

How much truer the diagnosis would be if signed, "Died because its grandparents had not been thoroughly enlightened as to the real character of the common and ever-increasing disease, syphilis."

112 West Forty-fifth Street.

X-LIGHT IN THERAPEUTICS.*

By CLARENCE EDWARD SKINNER, M.D., LL.D.
NEW HAVEN, CONN.

PROFESSOR OF THERMOTHERAPY IN THE NEW YORK SCHOOL OF PHYSICAL THERAPEUTICS; EDITOR OF THE DEPARTMENT OF THERMOTHERAPY IN THE "JOURNAL OF ADVANCED THERAPEUTICS"; PHYSICIAN IN CHARGE OF THE NEWHOPE HOT-AIR SANITARIUM, NEW HAVEN, CONN.; MEMBER OF THE AMERICAN MEDICAL ASSOCIATION, AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION, AMERICAN RÖNTGEN RAY SOCIETY, AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE, YALE MEDICAL ALUMNI ASSOCIATION, ETC.

One of the happiest and most important events of modern medical history has been the discovery of the therapeutic value of the x-ray. As with many of the great therapeutical discoveries, the circumstances which gave birth to the event were largely accidental, and the extent of the outcome of the first x-ray treatment administered with therapeutical intent was entirely unpremeditated, almost unhoped for, and absolutely beyond the utmost limits of expectation. Empiricism has scored another victory against deductive science, but our patients afflicted with pathological processes amenable to x-ray therapy are revelling to-day in the results of an ability to cope with these conditions upon our part, which was absolutely beyond the range of human possibilities seven years ago, and which even one year ago was a consummation not even hoped for by ninety-nine one-hundredths of our colleagues.

Empiricism, which is but another name for the dictates of experience, governs the therapeutical use of the x-ray to-day. We know no more about the inherent nature of the agent to-day than we did four years ago, when its advent into the therapeutical world was heralded by the Selfridge case. We cannot, therefore, state by what specific actions or influences x-light accomplishes its beneficent work, but the grateful acclamations of the hundreds who have been lifted from the shades of pain and despair into the realm of comfort and continued usefulness are the outcome of a clinical experience which is ample enough and conclusive enough to warrant the assertion that a new era has been inaugurated in the history of the management of malignant disease, and which bids fair to revolutionize our methods of managing these cases.

---

*Read at the one hundred and tenth semi-annual meeting of the Fairfield County Medical Association, at Norwalk, Conn., October 14, 1902.

As the subject, in its details, is an unfamiliar one to most of you, and as the general practitioner's interest in the matter centers chiefly upon curative results and clinical possibilities, I shall have to treat it from a general rather than a specific standpoint, but if any one should desire any specific information it will give me great pleasure to answer his inquiries during the discussion.

X-light has been found to be of value in the treatment of acne, psoriasis, eczema, rheumatism, some forms of neuralgia, neuritis, anthrax, lupus, and cancer.

Its use in the five first-mentioned conditions is still in the experimental stage, but the work done by Beck, Pusey, Morton, Snow, Allen, Montgomery, Schmidt, and others is sufficient to demonstrate that the agent possesses active curative influences which, in some cases at least, have resulted in the recovery of the patient after every other known means of benefit had failed. At present, however, the x-ray appears to have but a doubtful chance of becoming an active competitor of other methods of treatment in the majority of cases of these diseases.

In neuritis, two or three very striking instances of happy curative effects have come under my observation, and investigations along this line are now under way. The indications are that x-light will soon have a place in the treatment of this affection.

Several cases of anthrax have been subjected to the influence of this agent, and in a few instances results have followed which equal in attractiveness those attained in any pathological field to which radiotherapy has been applied. I know of one case in particular in which the curative effect appeared so magical that the operator hesitated to publish it, from a fear that he would be accused of romancing. The steadily-increasing accumulation of clinical experience will bring the matter to light in the near future, however, and ample grounds are at present available for believing that the knife will retain its large prestige in the management of this disease but a short time longer.

That lupus, both vulgaris and erythematosus, is amenable to x-ray therapy in the majority of cases is now a matter of common knowledge among those who are using this agent extensively. The curative effects are usually greatly intensified in this disease, and also in some cases of epithelioma, by combining with it the static brush discharge, with the patient insulated negatively. This has been denied by some operators, and one gentleman has carried his antipathy toward the brush discharge so far as to state as his belief that it always aggravates the trouble and should never be used. This sentiment, however, is unquestionably an erroneous one, as the addition of the brush discharge to the x-ray treatment of these cases has been adopted repeatedly at the x-ray clinic of the institution in New York with which I am connected, with none but good results. Professors Snow and Geyser, who have charge of this clinic, have reported cures following the use of this therapeutical combination, have exhibited some of their cured patients, and have never seen any evil results attributable to the brush discharge when thus employed. Personally I have enjoyed the privilege of watching the progress of these cases, have used the brush discharge upon my own patients with beneficial results, have yet to see any evil influences justly traceable to this modality, and shall use it again in appropriate conditions.

The interest in x-ray therapy of the profession at large, however, is centered more particularly upon the place it occupies in the management of cancer, and the justification of this interest is found in the fact that in this field it has won most enduring laurels.

Probably no event since the discovery of the value of antisepsis has attracted so much attention from medical men and laymen as the discovery of the power of the x-ray to overcome this disease. The announcement of the fact was first met by derisive incredulity; next by unwilling admission that beneficial results had certainly been observed simultaneously with the administration of x-ray treatments to sores that seemed to be cancerous; and, finally, before an overwhelming mass of clinical demonstration, skepticism has given way to amazed conviction.

It is not difficult to appreciate the incredulous attitude of the medical mind in this connection. From time immemorial, cancer has ultimately destroyed 70 per cent. or more of the total number of its victims, in spite of any measure that could be applied for its relief, surgical or medicinal, and whatever the stage of the disease at which it came under treatment. Probably no other disease, with the possible exception of pulmonary tuberculosis, has been looked upon with so much hopeless dread and horror. Therefore, when the statement was made that x-light, which had not been previously known as a therapeutical measure at all, would not only entirely remove this hitherto intractable condition in many cases, but would accomplish the result without even producing discomfort on the part of the patient, it is not strange that the tidings should be looked upon as altogether too good to be true.

Four hypotheses have been advanced as explanatory of the remarkable influence which x-light exercises over malignant neoplasms.

The first is that the curative process is brought about through stimulation of the reparative functions, dependent upon the induction of inflammatory reaction, x-ray dermatitis—a cauterant action in short.

Now, although in some cases the curative process is unquestionably hastened by inducing some dermatitis, and in still others benefit is apparently not susceptible of induction until dermatitis has been provoked, yet that the *modus operandi* of the x-ray cure of cancer is not through a cauterant action is proven by the large proportion of cases which recover without any evidences of dermatitis having obtained throughout the entire course of recovery. One of the most remarkable, if not the most remarkable, of the x-ray cures of cancer so far recorded was of this class. A still further evidence against the cauterization view is that sloughs are observable in only a small minority of cases, which would not be true if cauterization explained the matter.

The second and most attractive of the theories which have been advanced as explanatory of the phenomenon assumes that it is produced by reason of direct destructive influence, exercised selectively upon tissues of aberrant development and low vitality. That destruction of diseased tissues does frequently take place, accompanied, especially in the deeply-seated malignant processes, by a systemic toxæmia of variable degree, is unquestionably true, but if this were the essential element in the induction of the beneficial influence, it would constitute a clinical phenomenon of uniform and constant occurrence, and in the majority of cases this does not hold good.

The third explanation involves the contentions that cancer is a disease of parasitic origin, and that *x*-light inhibits or destroys the parasite. The most prominent fact militating against this theory is that, if cancer is caused solely by a pathogenic organism of this nature, and if this organism is susceptible of inhibition or destruction by *x*-light, then all cases of cancer should be curable by the agent, and clinical experience does not show this to be true. It is conceivable, however, that *x*-light, while not inherently and directly fatal to a parasite, might be capable of so affecting the tissues forming its pabulum as to render them unsuitable for its development, and, up to the present time, there is nothing in the clinical history of *x*-ray therapy in cancer which would be totally incompatible with this modification of the parasitic theory.

The fourth hypothesis assumes that malignant degeneration is simply a departure from the normal of developmental protoplasmic activity—a reversion to a more primitive cell type—dependent upon deeply seated constitutional idiosyncrasy and local irritation; and that the character of the vibration period, wave length, and amplitude constituting *x*-light possesses the power so to influence molecular motion as to overcome the aberrant tendency of cell development and restore the normal characteristics of the formative function. That a factor involving some constitutional idiosyncrasy as regards the metabolic processes concerned in cell development demands consideration is evidenced by the fact that all cases do not respond to *x*-ray therapy in the same degree and manner, and that some do not respond at all, while the conditions surrounding these different patients, as far as the pathological phenomena and their management is concerned, are apparently identical in all demonstrable respects.

If this is the true solution of the problem, it would be expected that *x*-light would inhibit the malignant process from further inroads upon sound areas, that the foci of degeneration would become surrounded or encapsulated by normal tissue, and, as a large proportion of the erring cells, forming the original mass, would inevitably have become degenerated beyond the possibility of redemption, that the diseased area would thereafter remain as a quiescent tumor, slough *en mass*, or undergo a process of simple atrophy, terminating, at least sometimes, in complete disappearance; and these are precisely the variations which we encounter in the clinical conditions. More light upon the etiology of cancer must be secured before the question of the *modus operandi* of the results of *x*-ray therapy can be settled.

I will state in this connection that *x*-light has not been proven to be directly bactericidal. Upon some of the common pathogenic bacilli and cocci it has, on the contrary, been proven to possess absolutely no demonstrable lethal influence.

We are frequently confronted with the query "Will not cancers that have been cured by *x*-rays ultimately recur?" and we are obliged to answer that we do not know. Enough time has not yet elapsed to determine this point. Less than 5 per cent. have so far shown any tendency in this direction, and in the instances in which the accident has obtained, it has proven to be readily manageable by an additional course of *x*-ray applications. Recurrences, at present, appear to be due to premature discontinuance of the treatments, or to the use of a tube of too low a vacuum, whereby a sufficient degree of penetration has not been secured to influence the deeper portions of the growth. The parts of a malignant process which it is most necessary to influence are the peripheral regions where the degenerative tendency is involving additional tissue areas; hence the rays employed should exhibit sufficient penetrative power to pass clear through the affected tissues and reach the remote ramifications of the growth, thus limiting the spread of the disease.

Even if they do recur, however, it seems at present to mean merely that another course of treatments will be necessary, the patient having been maintained in a condition of at least seemingly perfect health in the meanwhile. Any victim of cancer would be more than happy to undergo a course of *x*-ray therapy every six months if necessary, if this result could be attained thereby, and when we compare the poor showing of other measures, in affording even temporary relief, with the results attributable to *x*-light, the question of recurrence appears hardly to be worth a discussion from a purely clinical standpoint. There is certainly nothing to warrant the reproach upon the fair fame of the agent which is sometimes implied by the query.

For the purposes of *x*-ray therapy it is desirable to divide cancerous processes into two classes: those affecting the superficial soft tissues, and those involving the deep tissues and bones.

For the management of cases belonging in the first category *x*-light has almost entirely superseded the knife and caustics with those of us who are clinically familiar with the agent. Hundreds of cases have been treated, and statistics at present available indicate that the proportion of cures effected will exceed 80 per cent.

But a short time since it was generally believed that only the superficial forms of cancer were amenable to the curative influence of *x*-light, and enough work has not yet been done upon deeply-situated malignant growths to produce conclusive evidence as to the extent of the beneficial influence obtainable here. Indeed, comparatively few men have treated this class of cancers at all, but enough evidence is at hand to prove that some benefit can be secured in the majority of cases, and that a certain proportion of them are susceptible, apparently, of entire restoration to health.

I was first led to believe that deeply seated cancers might be amenable to *x*-light, by my conviction that the beneficial influence which the agent undeniably exercised upon the superficial form was due to some inherent corrective power which the *x-ray* vibrations exerted upon the developmental processes of the aberrant cell elements constituting the malignant tissue. I have never considered the effect to be due to ozone formation, electrification, or electrolysis of the elements of the growth, the deposition of any acid upon the sore, or any other of the several explanations which have been advanced to the exclusion of a *specific influence of x-light*. We have used all these means before, but they did not cure cancer until this agent came upon the scene.

With a good high-vacuum tube, one that forces back a spark-gap of not less than 4 inches, rays can be produced that penetrate clear through the body; hence a malignant growth in their path could not fail to be influenced by them, if *x*-light is capable of exerting influence.

At the annual convention of the American Electro-Therapeutic Association in September, 1902, I reported in brief detail thirty-three cases of deeply-seated cancer which I had had under treatment during the preceding nine months. As these cases will be published in full with the transactions of the association, I will not repeat the histories here, but will summarize the clinical results obtained and the conclusions deducible therefrom. For convenience' sake these cases were considered in five groups. The first consisted of nine cases, in which various deeply-seated localities were involved, and which had reached a fatal termination; the second, of four cases in which bony tissue was affected; the third, of nine intraabdominal cases still under treatment; the fourth, a series of ten mammary cancers; and the fifth was constituted by one case of sarcoma of the neck. Since then one patient classed in the third group has died, so that the first group will now consist of ten cases, this figure representing the total number of deaths up to the present time. The clinical data are as follows:

Complete disappearance of the malignant process has apparently been secured in three cases; continuous reduction in the size of tumor up to the present time in thirteen; temporary reduction with subsequent increase in one; permanent arrest only of growth in two. There was no effect positively demonstrable upon the size of the lesions in fourteen.

Complete permanent relief of pain was secured in fourteen cases; complete temporary relief in two; partial relief in eight; no relief whatever in four, and in five there had been no pain.

The general condition of the patient was permanently improved in eleven; temporarily improved in eight; not influenced at all, apparently, in eight; and in six the general condition was not noticeably impaired when the patient came under treatment.

A gain in weight was evident in six; no influence in this direction apparent in twenty-seven.

Hemorrhage was lessened in eight; uninfluenced in one; and in twenty-four there had been no hemorrhage.

Evidences of systemic toxæmia at some time during the course of the treatment were noted in fourteen.

In five cases there were discernible no evidences of benefit whatever. As three of these patients discontinued treatment after two or three séances, however, this statement can be significantly applied to but two of them.

Out of thirty-three cases, then, we have up to the present time, three apparent cures; thirteen that have been permanently benefited and are still improving, with good prospects of ultimate cure; twelve that were temporarily benefited; two that experienced no benefit whatever; and in three the treatment was discontinued by the patient before enough applications had been made to indicate whether or not any results would have been produced.

In estimating the absolute value of these results we must bear in mind that every individual one of these cases was inoperable, because of the advanced stage of the disease, and offered a hopeless prognosis both as to arrest of the disease or the attainment of euthanasia, under any other method.

The conclusions justified by the foregoing are as follows:

First, the pain of deeply-seated cancer is removable by *x*-light to an extent ranging from slight amelioration to entire disappearance, in a large proportion of cases, whereby the victim is enabled to spend what remnant of life is left him in comfort, and free from the pernicious phenomena which result from the continuous use of morphine, the only other therapeutical agent capable of producing even an approach to euthanasia in any appreciable number of cases.

Second, in many cases *x*-light is capable of exercising an influence upon deeply-seated cancer of sufficient intensity to retard markedly the progress of the disease, whereby life may be prolonged even in cases in which it cannot ultimately be preserved.

Third, in a proportion of cases, the figure representing which has yet to be ascertained, *x*-light possesses the power entirely to overcome deeply-seated malignant processes, restoring the patient to apparently perfect health.

Fourth, a small number of deeply-seated malignant growths exhibit absolutely no indications that they are susceptible of influence by *x*-light, and continue their ravages apparently unimpeded, ultimately compassing the destruction of the victim.

Fifth, phenomena consisting of chills, rise of temperature, etc., indicating systemic toxæmia, not infrequently accompany the treatment of malignant disease by *x*-radiance. This condition is probably due to the development or liberation of a toxin, the formation of which is, also *probably*, dependent upon retrogressive metamorphosis occurring in masses of tissue which have become too deeply involved in the malignant change to be susceptible of regeneration. This autoinfection is capable of reaching a degree of profundity sufficient to overwhelm the nervous system and destroy the patient, hence it is wise to interrupt the treatment temporarily when systemic toxæmia first appears, and allow the organism time to rid itself of the noxious accumulation before a further influence is invoked.

These conclusions, considered in connection with the uniformly gratifying results reported by nearly everyone as following the application of this agent to the external and superficial forms of this disease, would logically lead up to an attitude toward the use of the *x*-rays in cancer, which may be expressed as follows:

First, *x*-light can be relied upon to effect a greater proportion of cures of external cancer than any other measure or combination of measures now known, with the possible exception of massive mercuric cataphoresis as conceived, developed, and recommended by Massey.

Second, in all cases of cancer in which it may be considered advisable to use the knife, the influence of *x*-light in antagonizing cancerous degeneration may be looked upon as indicating its application for a time immediately succeeding the operation in all cases, and in some cases for a time immediately preceding the operation as well.

Third, in all inoperable cases the *x*-ray is indicated, because in a few instances it has apparently effected a cure of processes the most deeply located; in a considerable proportion of cases it has removed pain effectually, and improved the victim's general condition markedly, thereby rendering the remnant of his life comfortable; and, lastly, because it is the only measure that offers the victims anything whatever in the line of hope for ultimate recovery or prolongation of life.

In my opinion the reciprocal therapeutic relation of the knife and the *x*-ray, as regards the management of cancer, will be found ultimately to be an important one. The relationship may be considered as presenting three aspects; one of election by the patient, another of election by the *x*-ray therapist, and a third of necessity, of the existence of which the *x*-ray therapist and the attending physician jointly must be the judges.

The first-mentioned aspect will come before us most frequently in connection with the superficial forms of the disease, in which, as I have already stated, x-ray therapists now feel justified in abandoning operative intervention almost entirely. We take this stand because what we now know of the powers of the x-ray in this situation, considered in connection with what we also know of the frequency of recurrence after removal by the knife, leads us to believe that the x-ray should be applied for a time after operation in every case anyway, in order to eliminate as far as possible the chances of recurrence, and under these conditions the x-ray might as well be exclusively employed from the first. The only advantage offered by the use of the knife in these cases is that the malignant process is thereby gotten rid of *en masse* and at once, and the total length of time during which the patient is under treatment is somewhat lessened. Ordinarily, however, patients prefer giving the extra time to submitting to operation, and as the proportion of cures by x-light is so much greater than that resulting from extirpation, there is no reason why their election should not be respected.

The second aspect confronts us in connection with the more deeply-seated malignant processes, and its bearing upon the management of all cases is well illustrated by considering it in its relation to cancer of the female breast. These tumors may be divided, for purposes of prognosis under operative procedures, into two groups: those in which the demonstrable malignant involvement is confined to the gland, and those in which it has also invaded distant structures, as the axillary lymphatics.

The first-mentioned class offers a fairly hopeful prognosis under operative management, but even here no tissue extirpation of less extent than that demanded by the awe-inspiring Halstead operation can give much assurance in the way of freedom from recurrence. I have under x-ray treatment at the present time a patient who developed a small scirrhous of this class two years ago. Total extirpation of the gland and axillary lymphatics was done at once by one of the best surgeons in the country, and under the most favorable conditions. That the operation was exceedingly well done is attested not only by the operator's name, but by the visible traces of his work. Nevertheless, nodules began to appear along the lower border of the pectoralis major muscle and under the clavicle six months ago, to demonstrate that the fallacy of total extirpation alone obtains under even the most favorable of circumstances.

With reference to cases belonging to the second class, it is pretty generally conceded that recurrence is so sure to follow removal, that the best surgeons advise against operation under ordinary circumstances.

A number of cancers belonging in the first category have already been cured by x-light, and a large number are improving under treatment. I have never seen nor heard of a case that grew any worse under its judicious, skilful, thorough use.

In a few cases of the second class, entire disappearance of the axillary enlargement and notable diminution in the size of the original tumor—have followed the application of the agent, and in a much larger number a stay in the spread of the process has apparently been secured without any demonstrable reduction in size. On the other hand, a few cases have exhibited little if any evidence of beneficial influence having been induced.

The storm of enthusiasm engendered by the first successes of the x-ray in this field, led some of its advocates to demand that the knife be relegated to an unresurrectible oblivion, but, as clinical experience accumulates, we are becoming more and more impressed by a conviction that x-light and operative interference will ultimately join hands in dealing with the majority of cases of deeply-seated cancer. The principal reasons leading to the growth of this conviction are as follows:

First, the beneficial power of x-light seems to be inversely proportional to the amount of resistance interposed between its source and the tissue which it is desired to influence; hence, removal of the mass of the growth would allow the rays to act with greater concentration upon the remote threatening peripheral areas where the malignant process is spreading. It is further desirable to carry deeply as intense a concentration of the rays as possible, because there is no way of telling to how great a distance the minute channels containing aberrant cells may have ramified.

Second, if, as now seems probable, x-light produces its happy effect upon cancerous degeneration, at least largely through a physiologically corrective influence exerted upon aberrant protoplasmic acactivity, the figure representing its power for good will be inversely proportional to the amount of aberration present. Hence, it would appear to be desirable to eliminate from the problem as much of the cancerous tissue as possible, thereby confining the field of intended influence as nearly as possible to tissues exhibiting normal developmental tendencies. It would appear to be easier to prevent normal cells from becoming involved in the degenerative tendency, or to reclaim those in which this aberrant tendency was but slightly developed, than to eradicate the vicious characteristic from tissue in which it had already become firmly seated.

Third, in many malignant masses thus far treated, although the progress appears to have been stayed, and the tumor has usually exhibited some shrinkage in size, yet a considerable portion of it has still remained, apparently encapsulated by healthy tissue and rendered harmless as far as malignancy is concerned. The question naturally arises, however, "May not this hard mass, even though it has been rendered innocuous as far as its present inherent characteristics are concerned, act, at some time in the future, as a source of irritation merely by reason of its presence, sufficient to again set up the malignant process in the tissues of an individual who has already once demonstrated his susceptibility?" Many of us are inclined to consider that the less cancerous tissue we have in either an active or an extinct condition, the better, and to recommend extirpation.

The facts available at present, then, would indicate that x-ray therapy to the exclusion of operative interference is a justifiable election in mammary cancers of the first-mentioned class, but that they should be closely watched while undergoing the treatment, and subjected to extirpation to be followed immediately by x-ray applications, if they fail to respond to the rays alone. In cases of the second class the election should ordinarily be total removal of the gland and axillary lymphatics, to be followed by a course of x-ray treatments. In some cases a course of x-rays should also precede the operation. The principles of management suggested here apply to malignant growths occurring anywhere in the body.

The third aspect, in which the support of operative interference becomes a necessity, obtains in those cases in which benefit does not follow upon the use of the x-ray alone; in which the malignant characteristics continue to be manifest, in spite of it. A case should ordinarily not be considered as having assumed this aspect until the rays have been thoroughly tried for at least six weeks, then followed by a cessation of treatment for three weeks more. The reason for this is that some cases do not exhibit responsive phenomena until after several weeks of *x*-ray therapy, and a few cases have been treated in which response was not manifest until the applications were interrupted, but they made rapid progress toward recovery in the interval. The curative influence does not always appear to be suspended when the applications are discontinued, but sometimes continues to be active for weeks afterward.

Cases presenting this aspect may be divided into two groups: those in which the malignant involvement is sufficiently limited to admit of complete removal by the knife, even though the conditions are such as to render recurrence a positive certainty under surgical measures alone; and those in which the involvement is so extensive that only a partial extirpation would be practicable.

The plan of procedure in cases belonging to the first group is obvious, and consists of total extirpation, followed immediately by a continuance of the *x*-ray applications.

With cases belonging in the second group two courses are open to us. The first is to continue the use of *x*-light, with its usual accompaniment, under these conditions, of intermittent attacks of a systemic toxæmia, which has so far usually ended in the death of the patient from exhaustion; or to excise as much as possible of the cancer and continue the rays immediately afterward, in the hope that, by the removal of the bulk of the pathological tissue, the *x*-rays will be enabled to exert a more efficient influence upon that which remains.

The first course is usually pretty effectual in relieving pain and securing euthanasia; and when this result is obtainable most patients will prefer to omit operation and die in peace and comparative comfort.

Nothing can yet be said as to the results procurable by the second course, but some of us are of the opinion that what is known of the effect of *x*-light justifies presenting the alternative to the patient and abiding by his decision. The condition without it is one of absolute hopelessness, and we believe that victims in this extremity should be given the benefit of any ray of light, however small, that can by any possibility be construed into a hope of securing a betterment of their condition. It goes without saying that the patient should be made fully acquainted with the meagerness of his chances before making his decision in reference to submitting to operation.

Apparatus and technique are subjects of the highest importance in *x*-ray therapy, and a general knowledge of the prominent features involved is of considerable importance to the general practitioner, who usually sees these cases first.

Previous to a year ago it was commonly held that coil currents and low-vacuum tubes constituted the most efficient apparatus, and that it was necessary to induce dermatitis in order to secure a curative result. Since then most brilliant results have been attained by employing high-vacuum tubes excited by the static machine, and without the induction of any dermatitis whatever. The coil and low tube, therefore, no longer enjoy an exclusive prestige. The disappearance of some cancers is hastened, as previously stated, by setting up a dermatitis, and in these cases the greater volume of rays obtainable from a coil is undeniably of advantage, inasmuch as a burn will result from shorter exposures; but the advantage is more apparent than real, as far as ultimate results are concerned, as the high-vacuum tube excited by the static machine will burn quite as thoroughly if the time of exposure is lengthened and the distance from the patient's skin decreased. I make this statement with a conviction born not only of clinical observation, but of an emphatic personal experience as well. Individually, I treat superficial cancers with static machine or coil indifferently, and have not been able, as yet, to convince myself that the ultimate results differed in the least.

In the treatment of internal cancers, however, the coil is at a distinct disadvantage, and the speaker has discarded it entirely in this class of cases in favor of the static machine. The reason for the coil's inferiority resides in the shorter period of time required for the production of a dermatitis, as compared with the conditions obtaining when a static machine is used. As a rule, an exposure of ten minutes to rays excited by a coil is equivalent to one of fifteen minutes to those excited by a static machine, as far as liability to dermatitis is concerned. At first thought it would appear that the greater volume of the rays from the coil-excited apparatus would make up for the required lessening of the length of the time exposure, but, up to the present time, experience indicates that this inference is not correct. The beneficial influence of the rays upon internal cancer appears to be pronounced in proportion as the exposure is prolonged, and not to bear so much relation to the volume of the light. Hence, an apparatus like the static machine, which enables us to maintain the application of the corrective impulses for a period of time one-third longer than when the coil is used, exhibits advantages which cannot fail to make themselves felt in the long run. There is reason to believe that it may even, in some cases, constitute the difference between success and failure in securing favorable clinical results.

The static machine used in the treatment of the cases just quoted was an apparatus of the pure Holtz type, with twelve revolving glass plates thirty-two inches in diameter; the so-called Morton-Wimshurst-Holtz influence machine. The results attained with this excellent apparatus have led me to hope that I may be able to do still better with still more powerful radiance, and I have just purchased a machine of the same type having sixteen revolving plates, with which I shall treat my deeply-seated cancers in the future.

The use of a shield during treatment to protect the sound tissues surrounding a malignant growth is usually advisable when treating small external cancers. It may be composed of any substance capable of absorbing the rays, but tin or lead foil, gauge about thirty, is most widely adopted at present. Rubber sheeting, about one-quarter of an inch thick, is recommended by Dr. Albert C. Geyser of New York, and, besides affording ample absorption of the rays, exhibits the additional advantage of not attracting any of the exciting current from the terminals of the tube. Under some conditions, when tin is used, enough current will be diverted from the tube terminal to render impossible the proper lighting of a high-vacuum apparatus. The shield should be large enough to cover all parts of the body exposed to the rays, and near enough to the anode to make the production of dermatitis at all probable, and a hole should be cut in it of a size and shape that will expose the growth and about an inch of the apparently sound tissue contiguous thereto. When treating internal cancer, a shield is, of course, uncalled for and useless.

In treating cancer of the uterus some operators use a speculum to distend the vagina, on the ground that it is thereby possible to bring the rays into direct contact with the growth and secure a greater curative influence. I have never adopted this plan, because a vagina susceptible of distension sufficient to bring the whole of the diseased tissue within the field of application is a rare phenomenon. The peripheral portion of the growth in which the process is spreading is that which it is most important to bring under the influence of the rays, and that is the very portion which the speculum fails to expose. Before reaching these parts the rays must pass through the perineal tissues the same with as without the speculum, hence, so far as securing material arrest of the malignant process is concerned, I fail to see in what way it offers any advantage, except when the growth is small enough to render adequate exposure possible. If the growth is small enough for this, it would probably be better not to depend upon *x*-rays exclusively, but to remove it with the knife first, and ray it afterward, or subject it to massive mercuric cataphoresis.

Unless he is unusually susceptible, the *x*-ray therapist will not require protection for himself, as the locating of the tube, placing of the shield, and all other procedures requiring him to remain in the field of threatening influence are accomplished before the tube is lighted. In some cases, however, a protection is necessary, especially for the hands, and I have used ordinary gloves, backed with rubber sheeting one-eighth of an inch in thickness, with entirely satisfactory results. As I have said previously, the rubber is efficient in absorbing *x*-light, and a glove so constructed is fairly flexible and easy to manage.

In conclusion, I wish to state most emphatically that the therapeutic application of the *x*-ray should be intrusted, at the present time, only to the hands of operators who are skilled and experienced in this particular line of work, when it is possible to secure such, as the difference between efficient and faulty technique will frequently constitute the difference between success and failure in clinical results, as well as between safety and danger to the patient.

TYPHOID GANGRENE.

By CHARLES E. NAMMACK, M.D.
NEW YORK.

VISITING PHYSICIAN, BELLEVUE HOSPITAL, NEW YORK; PROFESSOR OF CLINICAL MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE, NEW YORK.

THE appalling complication of typhoid fever which forms the title of this paper is fortunately rare. Flint, whose observant eye missed very little at the bedside, never saw a case. Prior to the publication of Keen's excellent monograph,[1] a few contributions to the subject had been made, and are quoted by Keen, who brings the matter down to 1898. The term gangrene, as used in this article, excludes the familiar and frequent bed-sores. Its possibility, in mild as well as in severe cases, should always be borne in mind, especially at that period of typhoid when recovery seems to be a near event. Its commonest time of occurrence is the second and third weeks, during which time $39\frac{2}{10}$ per cent. of the 148 recorded cases occurred, the others ranging from the fourteenth day to the seventh week. The occurrence and date of onset are determined by a combination of factors, *i. e.* weak heart, sluggish circulation, general enfeeblement of mind and body, obstruction of the blood vessels, either as a result of arteritis or of autochthonous thrombosis, and the evil effects resulting from a diffusion of the bacilli and their toxic products throughout the tissues.

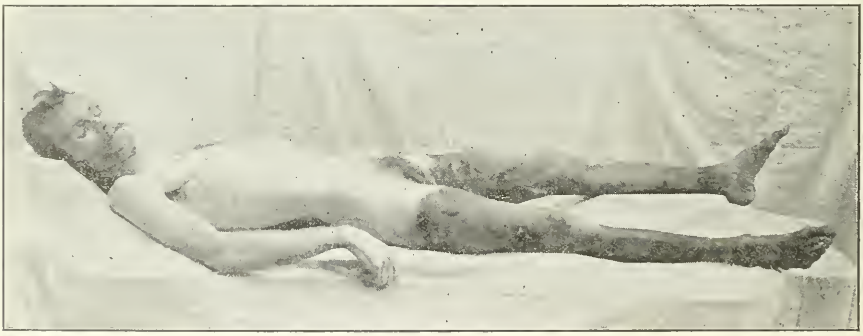
The operation of these causes results in the occlusion of a vessel by coagulation of its contents and thickening of its wall, which produces, sooner or later, a thrombus, with complete interruption of the circulation. It is probable that a diseased condition, both of the blood and of the blood-vessel wall, is necessary for the production of thrombosis The bacillus of typhoid circulates in the blood, and is capable of producing disease and death of the corpuscles, thus liberating the fibrin ferment which they contain, and the union of this ferment with the fibrinogenous ferment of the blood induces coagulation.[2] In grave infections the endothelium of vessels undergoes fatty degeneration and is desquamated. Every lesion of the wall of the vessel forms a halting point for the accumulation and subsequent dissolution of the corpuscles. Other changes are produced in the walls of the arteries by the presence in them of typhoid bacilli. These set up a specific infective typhoid arteritis, and this is believed, at the present time, to be the principal cause of gangrene of the extremities in the course of typhoid fever.[3] These changes more readily occur in individuals already the subjects of arteriosclerosis, amyloid degeneration, syphilitic infection, mechanical or chemical injury, or inflammatory process which injures the intima of the vessel. Several investigators have claimed to have cultivated the typhoid bacilli from the walls of the arteries, and two forms of arteritis have been described: first, an obliterating form, and, secondly, a parietal form. In the first, the lumen of the vessels and its branches is gradually obliterated and the gangrene is correspondingly slow and not sudden, as in embolism. As a rule, therefore, in arterial thrombosis the gangrene is dry, but occasionally the vein also becomes obstructed and moist gangrene develops. In the second, or parietal, form of arteritis, thrombosis does not usually occur, and these cases generally recover.

The cause of gangrene in typhoid fever, then, may be summed up in the single phrase—obstruction of the circulation. This depends upon four factors, the altered blood, the weakened heart, the mechanical difficulties of the circulation in distant parts, and, lastly, the local effects of the bacillus itself. Four different varieties of obstruction may exist and sometimes coexist: First, arterial thrombi of cardiac origin; secondly, autochthonous thrombi in the arteries; thirdly, autochthonous thrombi in the veins, and, fourthly, thrombi in the small peripheral vessels.

As a rule, typhoid gangrene affects the lower extremities either singly or consecutively. In the case about to be related, however, the process invaded both legs simultaneously, and the clinical diagnosis was arterial thrombosis of autochthonous origin, involving the aorta at its bifurcation, This gave us the clinical picture of dry gangrene, beginning in the distal parts and extending upward to the upper third of both thighs. Later probably, from the supervention of venous thrombosis as well, moist gangrene began to appear, at first in the proximal parts.

Patrick McG., twenty-nine years old, laborer, married, was admitted to Ward 17, Bellevue Hospital, October 30, 1902. His father died from consumption and hard drinking. One sister died from spinal meningitis. Three brothers and two sisters are alive and well. Patient drinks beer and whiskey occasionally, very rarely to excess. He denies any venereal disease or other serious illness.

On October 12 began to suffer from anorexia, headache loose bowels, with foul-smelling greenish stools, vomiting, cough, and expectoration. On October 26 a physician at his home found his temperature to be 103°, sent a Widal test to the Board of Health laboratory, which gave a positive reaction in dilution of 1 to 20, and ordered quinine in doses of twenty-four grains daily for three days. At the end of that time patient felt much better, and was allowed to get up and go out to the toilet. Next day he was much worse, and complained of numbness in, and coldness of, his feet. These symptoms being progressive, an ambulance was called. On admission there was no evidence of either valvular or myocardial disease. In addition to the ordinary signs of typhoid, there were noted coldness of feet, diminished sensibility in feet, slight pulsation in abdominal aorta, and a noticeably rapid clotting of blood drawn for examination by puncturing the ear. A small incision was made into the leg without producing any bleeding. A positive reaction to Widal's test was obtained, within a time limit of one hour, in dilutions up to 1 to 200. Next day, November 1, discoloration appeared in feet and legs. No pulsation could be felt in femorals or in leg vessels. Discoloration rapidly ascended to the upper fourth of each thigh, simultaneously and symmetrically, and did not involve penis, scrotum, perineum, or buttocks. The femoral arteries felt hard and cord-like. Rectal examination showed no pulsation in the internal pudic arteries. The purplish discoloration gradually deepened in color, but did not extend, and patient did not complain of pain until November 4, when severe shooting pains in ankles appeared and required use of morphine. On November 3, 10 c.c. of blood were taken from vein, for bacteriological examination. Cultures were reported as sterile. No pulsation in the abdominal aorta could now be felt. On November 7 blebs began to appear on both thighs near the lines of demarcation, and thenceforward progress was rapidly and steadily downward, moist gangrene having supplemented the arterial dry gangrene, until the patient died at 3 A.M. on November 14, 1902. There was no paralysis of either bladder or rectum up to the time of death.



All our powers of persuasion were unavailing to secure permission to hold an autopsy, without which our case lacks much scientific interest. It is merely offered for record to renew in our minds the necessity for caution in prognosis in typhoid fever until the time for failure of the circulation has been safely passed. Of course, it might have been impossible for autopsical research and bacteriological study to reveal the exact method of formation of the thrombosis,[4] yet their absence is regrettable. The accompanying illustration fairly represents the bedside picture. The rarity of the condition is attested by the fact that no case of arterial thrombosis was found in 2,000 autopsies in Munich on typhoid-fever cases, although the same series yielded fifty-nine cases of thrombosis of the femoral vein.

THE ETIOLOGY OF RELAPSE IN TYPHOID FEVER.*

By H. N. Rafferty, M.D.

Robinson, Ill.

By the term "relapse" in typhoid fever is meant a repetition of a part or the whole of the morbid process, after the temperature has reached the normal, and all the other symptoms of the primary attack have practically disappeared. Therefore, we must differentiate on the one hand from a simple recrudescence, or relighting of the primary attack, and on the other from a true recurrence, or subsequent infection from some extraneous cause, in spite of the immunity which is usually afforded by the one attack.

We are all familiar with the recrudescence, generally occurring during early convalescence, and characterized by a sudden, but usually brief, elevation of temperature, following excitement, fatigue, or error in diet. And, likewise, we occasionally see or hear reported a second or third attack of enteric fever, separated by intervals of five, ten, or fifteen years, as the case may be. According to general observation, these second attacks are milder in type than the primary one, and more common in men than in women—this last fact being due, no doubt, to the increased exposure to infection of the male sex.

But while these circumstances to which we have just referred are fairly common, and generally easily explained, the occurrence of a true relapse, after an absence of fever and other symptoms for a period varying from a few days to several weeks, although met with in from 7 to 20 per cent. of all cases, is always of particular interest to even a slightly inquiring mind, and often unexplainable to the most inquisitive.

As regards the etiology of the "primary" attack, there has always been more or less discussion. But it is now tolerably well established that the typhoid bacillus may gain entrance to the body not only through the alimentary canal, in our food and drink, but also occasionally through diseased tonsils or the lower respiratory tract when not thoroughly desiccated and air-borne. Concerning the latter belief, R. H. Quill[1] has recently reported an epidemic in a large military camp, among Boer prisoners, in which the surrounding guards were infected in spite of the fact that all the water avenues were efficiently guarded, making the water-borne origin impossible. He thinks the dust and wind served to carry the bacilli from the latrines and urinals. It is further conceded that no matter what the avenue of entrance may be, the disease is primarily a systemic infection.

---

*Read before the Crawford County Medical Society.

The examination of the blood of typhoid-fever patients for the bacilli at first gave exceedingly variable results, and up to the present time very little dependence has been placed in the method, except by laboratory enthusiasts. But systematic investigations of late have definitely proven that the bacillus frequently exists in the general circulation in enteric fever, and make it very probable that in every case it is present in the blood some time during the course of the disease.

Courmont[2] has found the bacilli in pure culture in blood from a vein of the arm in several grave cases, from the first to the twenty-third day, and says the same is true in relapse. The fact that the organism has been found in the blood from the roseola; in the urine, meninges, middle ear, pelvis of the kidney, lungs, and in the aborted fœtus, both during and after maternal typhoid fever, can be explained only on the ground that it is deposited in these various seats by the blood. And this brings us quite naturally to the etiology of relapse, since the only plausible theory for this occurrence seems to be that it is a reinfection from some bacillary nidus within the patient's body, which during the well interval, whether of long or short duration, has remained localized and quiescent.

It is probable that this reinfection may take place (1) by inoculation of healthy intestinal glands with sloughs thrown off from those first infected; (2) by a deposit of bacilli in the gall-bladder, with or without a resulting cholecystitis, and later an expulsion of this colony with bile into the duodenum, and (3) by a colonization of bacilli in the spleen, as it has been noticed that occasionally in relapse the splenic enlargement does not subside with the fever of the primary attack.

Zenetz[3] several years ago expressed the belief that in the cases in which relapse occurs there is no tendency during convalescence to regain the weight lost during the primary attack, and argued from this point that relapse is not a reinfection, but that these patients have never really recovered from the disease. This view certainly does not hold good in many cases, as we frequently see the relapse after at least a portion of the weight has been regained, and sometimes when the usual standard of health has been reached. He very properly asserted, however, that a case of enteric fever is never free of danger of relapse until a time at least equal to that of the entire febrile period has been passed.

In a series of 1,626 cases, Berg[4] mentions a relapse after seventy-seven days of normal temperature, showing an interval double the time of the original febrile period.

The recent Johns Hopkins Hospital Report[5] is responsible for the statement that "high authorities consider the gall-bladder as one of the surest places to obtain a pure culture of the "Bacillus Typhosus," and in this connection it is well to mention Camac's[6] report in 1899, of forty-three cases of cholecystitis complicating and following enteric fever, in thirty-four of which the specific organism was isolated.

Schlier[7] has recorded a fatal case of enteric fever in a man of nineteen years in which the autopsy showed a purulent cholecystitis with rapture of the gall-bladder and peritonitis. Fluid taken from the gall-bladder wall contained a bacillus resembling that of Eberth.

Merkel[8] reports a similar case in a man who developed icterus during convalescence, with peritoneal symptoms and death. He found an abscess cavity in the gall-bladder and under surface of the liver, with a phlegmonous inflammation of the cyst wall. There were no calculi, but the typhoid bacilli and staphylococci were found.

Malvoz[9] had a similar experience, in which, besides the usual lesions, he found numerous small ulcers on the inner surface of the gall-bladder, while its peritoneal covering and the adjacent colon showed inflammatory changes. In these lesions streptococci only were found.

McDaniel[10] and others have reported carefully analyzed cases of primary typhoid cholecystitis, without apparent intestinal lesions.

Going back ten years, we find that Chantemesse[11] maintained that the anatomical changes in Peyer's patches should not be considered an infallible criterion because of the fact that the bacillus had been found in pure culture in the various organs of the body, both pre- and post-natal, without intestinal involvement, and that it may remain latent in one or more of these organs, retaining its viability and virulence for a long period after the disease has apparently terminated. As regards, further, the longevity of the bacillus, in the intestine and in these various niduses, the living germ has been found in the bodies of men dead from enteric fever, three months after death, and various sequelæ, due apparently to infection with the specific organism, have occurred many years after the attack of enteric fever.

Eugene Wasdin[12] thinks there must always be a colonial development of the organism other than in the intestinal canal, as shown (1) by the presence of the bacillus in the blood before it is found in the intestinal contents, now appearing in the stools until the end of the first week, and (2) by the more or less marked colonization in the lung, attended by bronchial irritation, with cough and expectoration of the bacilli. Indeed, this observer has gone so far as to say he believes this lung colony to be the primary one; while Carnac[13] has recently declared the liver to be the primary center of infection.

You may say "enough of this theorizing—give us practical typhoid-fever data," and my reply lies in the fact that, undeniably, this same spirit of curiosity and investigation has served to make the term "enteric fever" a misnomer—to take it from the class of intestinal diseases and place it properly among the systemic infections, with the knowledge that the enteric lesion is secondary, and but one of several. The main object of this review is to point out the probability that a large percentage of relapses in typhoid fever is due to the gall-bladder and liver colonization, and subsequent reinfection of the duodenum and lower bowel with the bacilli-laden bile. In support of this belief I wish to consider briefly the case of a man who had a mild primary attack of typhoid fever, a complicating cholecystitis, an apparently complete recovery, and a typical relapse after an interval of thirty-five days.

C. O., age thirty-four years, was a perfect specimen of manhood, having never before been sick. He was first seen on October 11, 1901, when he had been sick one week, and presented a fairly complete picture of a mild attack of typhoid fever. Rose spots were found on the twelfth day, and the course of his illness was, as usual, up to the fourteenth day, when he was seized with vomiting, and some pain and tenderness over the gall-bladder region. The liver dulness was increased and the overlying muscles somewhat rigid. These local signs increased in severity up to the seventeenth day, when the gall-bladder could be palpated as a mass the size of a small orange, giving dulness on percussion, but no apparent fluctuation.

The temperature which had been 102° on the evening of the fourteenth day reached 103$\frac{3}{5}$° by the nineteenth, when, under an expectant plan of treatment, these symptoms abated, and convalescence was otherwise without incident, the temperature reaching normal on the twenty-third day. He was out in a week, and had resumed his occupation and usual habits of living when, on November 30, or six weeks after having discharged him, I was again called and found the patient had been having a little fever and malaise for the past week, culminating in a chill on the evening before. I found him in bed with a temperature of 102°, and, suffice it to say, he had a repetition of all the symptoms of the original attack, with splenic enlargement, bowel signs and eruption appearing on the tenth day. His highest temperature was 103$\frac{1}{5}$°, on the fourteenth day, and normal on the eighteenth, with perfect convalescence.

WOODWORTH BLOCK.

PASTEURIZED AND STERILIZED MILK AS A CAUSE OF RICKETS AND SCURVY.

By E. M. SILL, M.D.,
NEW YORK.

ATTENDING PHYSICIAN IN DISEASES OF CHILDREN AT THE GOOD SAMARITAN DISPENSARY; ASSISTANT IN DISEASES OF CHILDREN AT CORNELL UNIVERSITY.

As COMPARATIVELY little has been written on this subject, it may be of interest to the profession to hear the results obtained from feeding infants on the heretofore much-lauded sterilized and pasteurized milk.

I have taken a hundred and seventy-nine consecutive cases which have been fed during a period of from three to eighteen months, pasteurized milk being given for nine months of the year, while during the three summer months sterilized milk was given.

These observations have been made in a large dispensary where there is a well-equipped milk laboratory and where, during nine months of the year, the milk has been pasteurized and, during the three summer months, sterilized. It is all carefully modified to suit the age and condition of each child, and every precaution has been taken to make the bottles absolutely clean and sterile before using.

These bottles with pasteurized milk are given out each day by competent nurses.

I have examined the children so fed with the utmost care and have found in 97 per cent. of the cases unmistakable signs of rickets or scurvy, most of the cases being rickets or a combination of rickets and scurvy, the one merging into the other. About forty of these children had from five to seven feedings of the sterilized or pasteurizd milk, according ing to the time of year, each day, supplemented by breast feedings. These all had signs and symptoms of rickets, although not so marked as in those who were fed exclusively on pasteurized or sterilized milk.

The changes which were most frequent were beading of the ribs, pot belly, sweating about the head, flabby muscles, craniotabes, and restlessness at night. The later changes were, in addition to those already enumerated, large, square head, enlarged epiphyses, delay in the eruption of the teeth, constipation or diarrhœa, malnutrition, bow legs, kyphoses, chicken-breast, horizontal ring, and open fontanelles.

An infant food must take the place of and simulate mother's milk to be an ideal food, and in order to do this it must be of animal origin, it must not be heated above blood heat, as a temperature much above that disorganizes the albuminoids and the mineral constituents; it must contain all the ingredients of mother's milk in the same proportions; it must contain no ingredients not found in mother's milk.

The aim of sterilization and pasteurization of milk has been to destroy disease germs, and preserve it,—that is, to keep it from turning sour.

Uncontaminated milk is necessary, we admit, for successful infant feeding, but contaminated milk, no matter how carefully modified and pasteurized, will cause disordered digestion and improper assimilation in the young child.

Sterilization or pasteurization of milk makes it a dead, preserved food. Mother's milk, on the contrary, is a live, fresh food.

Winters says: "I have seen scurvy where pasteurized, modified milk had been the only food. Recovery was rapid with the continued use of the same food raw." Again he says, "Fresh, pure milk is not improved by pasteurization; it is not more digestible, and it is in no way a better food for an infant."

Sterilized or pasteurized milk is to the infant what canned or salt food is to the sailor.

It is unnecessary to pasteurize milk to destroy disease germs when a pure milk supply is provided for, and this can be practically done, by having the herd frequently subjected to the tuberculin test to exclude tuberculous cows. The cows must be groomed, the teats and the udders and the milkman's hands thoroughly washed and dried before milking. The milkman should wear clean, washable clothes, and the milking should be done in a building away from the stables.

The milk should be received into sterilized quart bottles, which are then tightly sealed, labeled with the dairyman's name and the date, and cooled immediately to a temperature of 40° F.

Experiments which have been made at the Yale University Agricultural Experiment Station show that when milk is cooled to 40° F. all bacterial growth is at once arrested, and continues so long as the milk is kept at that temperature. Milk has been kept sweet in this way for several weeks.

In conclusion: I would say cow's milk is generally acknowledged to be the best substitute for mother's milk, when properly prepared, but cow's milk is not bettered by sterilization or pasteurization; on the contrary, this treatment undoubtedly makes it the direct cause of rickets and scurvy and kindred diseases in children.

The object of pasteurization can be safely accomplished, in the opinion of the writer, by the above-described care of the milk. It therefore appears that this subject warrants a more careful investigation by the profession, as it is a vital question in this city, since hundreds of infants are being fed on sterilized or pasteurized milk.

THROMBOSIS IN CONNECTION WITH TYPHOID FEVER.

THE cause of thrombosis after typhoid fever is not definitely known, although the condition is usually ascribed to infection of the wall of the veins. A great deal of interest has been evinced with respect to the etiology of thrombosis or phlebitis, as a sequence of typhoid fever in England since the South African war, owing to the fact that it occurred far more frequently in South Africa than in England. Many observers attribute its prevalence to the consumption of canned foods, which served as the mainstay of the British Army when far from its base. Dr. H. D. Rolleston considered it was due to diminished resistance, brought about by the hardships incidental to guerilla warfare, and that the condition was one approaching scurvy.

Professor A. E. Wright, the discoverer of the antityphoid serum, and Dr. H. G. Knapp recently read a paper before the Royal Medical and Chirurgical Society, in which was recorded the result of observations with regard to the connection between thrombosis and typhoid fever. These observations dealt with the following details: The blood (*a*) in typhoid-fever patients in the acute stage of the disease, (*b*) in convalescents from typhoid fever, and (*c*) in normal persons. In each case the coagulation time of the blood, and its contents in lime salts were measured. The investigators then described the method of determining (1) the coagulation time of the blood, and (2) the amount of calcium salts present in the blood. The results of the blood examinations undertaken on normal men showed that there was between different individuals, as well as between the blood drawn off at different times from the same individual, a considerable difference, not only with respect to the blood coagulation time, but also with respect to the content in lime salts. It was found that the coagulation time might, in the normal male adult, vary between three and one-half minutes and fifteen minutes, and the minimum strength of oxalate of ammonium solution required to avert coagulation from 1 in 800 to 1 in 2,000.

Of importance in connection with the method of measuring the contents of the blood in lime salts was the fact that a blood which contained less calcium salts than a control blood was not always less coagulable; nor again, was a blood which contained more lime salts necessarily more coagulable than the control. The content of a blood in lime salts, as estimated by this method, was, in fact, far from being an index of its coagulation.

The results of the blood examinations undertaken upon typhoid-fever patients during the acute stage of the disease showed a general diminution of blood coagulability. The results of the blood examinations undertaken upon convalescents from typhoid fever showed a marked increase of blood coagulability. In eight cases, all of which were examined during the course of the pyrexia, and after the return of the temperature to the normal, it was found that the coagulation time of the blood was, on the average, four and one-half times shorter in the convalescent stage than during the course of the fever. In four of these cases blood coagulation was abnormally rapid, and in each of these femoral thrombosis had supervened, and these were the only cases among those examined in which it had occurred.

The results of the calcium salts estimations showed that the average content of the blood in lime salts, as estimated by the oxalate method, was in the case of convalescents from typhoid fever about twice that of the normal blood. It had been pointed out by Wooldridge that there supervened upon the "positive phase" of increased coagulability, which culminated in the thrombosis, a "negative phase" of diminished or abolished coagulability. By reason of the supervention of this "negative phase" the thrombus, when once formed did not receive any further accretions of fibrin from the circulating blood. Quite different were the circumstances when the blood maintained its original coagulability. Here, as soon as any blood flow was re-established past the clot, additional fibrin would be deposited, and the thrombus would grow larger and firmer until at last it was converted into a solid plug of "white blood-clot" which definitely blocked the vessel. Probably in this way were sown the seeds of the permanent trouble so often seen after thrombosis in typhoid fever. The treatment proposed by Professor Wright and Dr. Knapp was to place an obstacle in the way of this deposition of fibrin by diminishing the patient's blood coagulability, and with this view, a decalcifying agent—citric acid—was administered with the desired effects. The authors conclude that the increased coagulability during the convalescent stage of typhoid fever might be dependent upon an excess of lime salts. This excess was probably derived from the milk which, for the most part, constituted the exclusive dietary of the patient. Cow's milk contained 1 part in 600 of CaO as compared with 1 part in 800 contained in lime water. If the milk dietary of the typhoid-fever patient was the key to the problem of the frequency of thrombosis in the period of convalescence a clue had, perhaps, been obtained also to the resolution of certain other problems, in particular the problem of the frequently beneficial effect of a milk dietary on "serous hemorrhage" from the kidney, and the comparative rarity of thrombosis after acute fevers, such as Malta fever, in which a milk dietary was not imposed upon the patient. At the same time indications for the prophylaxis and after-treatment of thrombosis were obtained both when it occurred in connection with typhoid fever, and when it occurred in connection with other diseases. The remedial measure which would seem to be indicated was the exhibition of citric acid. The same treatment, initiated as soon as the danger of intestinal hemorrhage had been surmounted, would be appropriate for prophylaxis of thrombosis in typhoid fever, or, as an alternative, with a view to restrict the intake of lime salts, a partial decalcification of the milk might be undertaken. The partial decalcification in question could be readily effected by adding to the milk from 0.25 to 0.5 per cent. of citrate of soda—from 20 to 40 grains per pint.

If an excess of lime salts be the principal factor in the causation of thrombosis after typhoid fever, then it would seem as if the most rational treatment would be to diminish the blood coagulability by means of a decalcifying agent, of which agents citric acid is, according to Professor Wright, the most effective. Again, if the excess of lime salts be due to a milk dietary, it would certainly be advisable to partially decalcify the lactic fluid before the patient is permitted to take it. However, there are many diseases in which milk is the staple diet, and thrombosis seldom appears.

In the discussion which followed the reading of the paper by Professor Wright and Dr. Knapp, Dr. Ogle asked if the treatment by citric acid might not be attended by some danger of embolism, owing to the clot becoming dislodged from the wall of the vessel.

The paper is a somewhat noteworthy contribution to the medical literature of typhoid fever, and seems as reasonable an interpretation of the cause of typhoid thrombus as any yet given.

THE REPORT OF THE SURGEON-GENERAL OF THE NAVY.

The report of Surgeon-General P. M. Rixey shows the operation of the Bureau of Medicine and Surgery for the past year, the medical needs of the service for that ending June 30, 1904, and the medical statistics of the Navy for 1901. During the past year thirty-three applicants were examined for admission to the Medical Corps, and sixteen were found qualified. The most urgent need exists for an increase in that corps. For, while between 1897 and 1901 the personnel of the Navy has increased 70 per cent., and the various medical duties from 75 per cent. to 174 per cent., the personnel of the Medical Corps has increased but 15 per cent. The Surgeon-General says: "Congress, by wise legislation in raising the age limit for entrance and increasing the rank of Assistant Surgeons, has made it possible to fill the corps, and there are no vacancies. The hope entertained by the young medical officer just entering the service for future distinction has been so little realized, however, that the resignations for the year 1901 numbered five, nearly one-fourth of the number taken into the service in the same period. The reasons leading up to these resignations could be traced to dissatisfaction with the opportunities for purely professional work and advancement offered by a service overworked and undermanned. Lately two promising candidates before the Board of Examiners, after passing exceptionally brilliant examinations, refused commissions in the Navy, but accepted those offered by another branch of the Government service."

Moreover, great injustice will be inflicted in the near future upon assistant surgeons, who, at the time of accepting commissions, were virtually promised examination for promotion at the expiration of three years' service; which promise it will, however, be impossible to carry out under present circumstances. Conservative estimates place the needed accession in strength at 150, and it is urgently recommended that Congress be now asked to authorize an increase of at least seventy-five in the lower, or sea-going, grades, and it is further recommended that twenty-five be made surgeons, making the total number eighty instead of fifty-five now authorized by law, and the remainder passed assistant surgeons and assistant surgeons, making a total in these grades of 160 instead of 110. The other additions to the Medical Corps recommended are twenty-five pharmacists, an unstated number of contract dentists, and a corps of female nurses for the larger naval hospitals. With a view to training the newly-appointed assistant surgeons for the specialized work demanded by the Government service (especially necessary in view of our widely-distributed possessions, and of the fact that the naval medical officer must be his own consultant and laboratory expert) it is expected that a class will be assembled at the "Naval Museum of Hygiene and Medical School" in Washington, D. C., in October, 1902. With an increase in the number of medical officers it will be possible to grant periodical leaves of absence for study at medical centers, to enable officers to keep in touch with medical progress.

Heretofore much trouble has resulted from nonattention to medical and hygienic questions when the construction of vessels has been under consideration. As a general rule, the medical officer has first come into contact with the problems of ventilation, drainage, housing, and berthing of the crew, storage of food and water, etc., when ordered to a ship ready for commission, and one of his first duties has been to report on her defects in these particulars; defects not infrequently involving great expense to remedy, and sometimes impossible of change. These considerations have, we are glad to note, led to the Bureau's being granted representation, in an advisory capacity, in relation to matters of construction.

Ambulance and hospital ships are strongly endorsed "as a necessary adjunct to a fleet or station (and by hospital ship is means one that is equipped for hospital purposes only, and has the right to fly the flag of the Geneva Conference). . . . The late efforts to secure a hospital ship for the winter maneuvers in the West Indies, show conclusively how difficult it is to secure action till the time of need arrives, and how easy it is then to take everything for other purposes and leave the medical officer to combat the emergencies as they arise with what may be at hand."

During 1901 23,678 applicants were examined for admission to the service, of which 38.45 per cent. were rejected for all causes, 2.47 per cent. being for color blindness. Seven insane were committed to the Government hospital. Out of a total service strength of 26,101 there occurred: Epidemic catarrh, 1,315 cases; malarial diseases, 1,112; rheumatic affections, 778; wounds, 717; diarrhœal affections, 695; gonorrhœa, 617; contusions, 581; syphilis, 546; sprains, 492; and dengue, 427. Of 166 deaths, twenty-three were from drowning; twenty-two from pneumonia; seventeen from heart diseases; fourteen from typhoid fever; thirteen from pulmonary tuberculosis, and ten from local injuries. For every 1,000 men the figures for 1901 and 1900 were, respectively: Admissions for disease, 652.96, 688.90; admissions for injury, 113.78, 135.22; discharges for disease, 32.56, 24.66; discharges for injury, 4.76, 4.58; deaths from disease, 4.28, 5.01; deaths from injury, 1.90, 3.87; daily average of patients, 33.99, 34.80; average number of days for each case under treatment, 11.18, 15.41.

A number of special papers terminate the report. Medical Inspector Manley H. Simons discusses the sanitary aspects of the Isthmus of Panama. In November, 1890, when the *Enterprise*, with a crew of about 140, reached Colon at the height of the rainy season, the waters of the Chagres and Minde rivers extended well into the bay, and the health afloat and ashore was good. Late in December the dry season set in, and heavy trade winds flooded the harbor with green sea water, and drove back or covered up the muddy water. Within two weeks Chagres, or pernicious remittent, fever attacked the crew, and was very prevalent ashore. By the end of January fully half the crew had had it. Ashore many (principally Jamaica negroes) had died. Most deaths occurred in hovels built over the edge of the swamp between Colon and the back bay out of débris of burned houses and of poles cut in the swamp. Through the cracks in the floor table refuse and other filth were thrown, and the hogs made wallows there in which water stood long after the dry season had set in, thus making a fine breeding-ground for mosquitos, which swarmed after dark. The disease was also very fatal in a row of old houses opposite French Colon, built below the level of the railroad track over the shallow back waters of the swamp. The railroad physician pronounced it pernicious intermittent, but the French physician thought many cases yellow fever. On the *Enterprise* most cases were remittent; a few intermittent. At Panama, in November, the *Iowa* landed 276 officers and men for ten days. Five officers and sixty-seven men slept in the railroad station, a quarter to a half mile back from the harbor; the officers on the second floor, with mosquito nets, the men in an open room on the first floor, without nets. The mosquitos were very troublesome. The other officers and men slept in an open shed on the wharf, without nets, but were not troubled by mosquitos. Of this party two had remittent fever, one of the cases having probably been contracted in the town at night. At the station, one officer had light, and twenty-six men severe, remittent fever. The fever recurred, if at all, on the seventh or fourteenth days. Though it was the rainy season, ten days without rain had dried the pools and exhausted some cisterns. Owing to local prejudices, it is difficult to get the facts as to the prevalence of, and the mortality from, yellow fever, but the author believes it is not very prevalent, though Indians from the mountains quartered in old barracks are said always to develop it. Certainly hundreds of workmen on the canal died, but the probabilities are that most of the deaths were from pernicious remittent fever and dysentery. The former is so severe, and the gastrointestinal symptoms so pronounced, that a clinical diagnosis of it from yellow fever is impossible. Diarrhœa, dysentery, and simple continued fever are common and severe. Typhoid fever is, it is claimed, practically unknown. Smallpox was prevalent, but malarial fever occurred only among unacclimated government troops. Many valuable suggestions are made as to the hygienic precautions necessary if the Panama route be chosen. We should control at least three miles on each side of the canal, and police it thoroughly. The writer believes the pernicious remittent fever can be prevented, but it takes more quinine than can be borne comfortably if other measures are neglected. Mosquitos certainly carry the contagion, but flies and other vermin may also carry both it and yellow fever. He treats it by a saline, 60 cgms. of acetanilid, repeating the latter cautiously, in 30 cgm. doses, with caffeine, and by sponging with alcohol and cold water; when 100° is reached, 1.6 grams of quinine is given, with, four hours later, 1 gram or more of quinine; but if, meanwhile, the temperature has risen, the acetanilid and sponging are repeated, and 2 or 2.3 grams of quinine given. The temperature is generally over 105°, and there is diarrhœa and sometimes vomiting. Generally there is a forenoon and an afternoon exacerbation, but one nocturnal and two daily remissions may occur.

Assistant Surgeon Edward M. Blackwell finds elephantiasis in 10 per cent. of adult Samoans, involving, in order of frequency, legs, scrotum, arms, and mammæ; the labiæ once, the anus never. Scrotal hydrocele is more common than scrotal elephantiasis.

Assistant Surgeon Charles S. Butler describes the leper settlement at Molokai, Hawaiian Islands. He thinks the disease upon the wane. The diagnosis is made bacteriologically; a small, wedge-shaped piece of skin, with the subcutaneous tissue, is excised and triturated, with five or six drops of salt solution, to a soupy consistency, and smears are stained by Gabbett's method. As but one physician is employed at the settlement, and his time is fully occupied with clinical work, no records are kept and no scientific work attempted. At a local medical meeting the theory of infection via the mosquito was propounded, based upon the location of the initial lesions where mosquitos bite, and upon the finding of the microorganism in mosquitos from infected houses.

Surgeon John F. Urie found albuminuria in every one of thirteen cases of influenza; in amount from a trace to 1-4 of 1 per cent. After convalescence a decided show remained in four cases, a slight trace in five, and none in four. He adds: "The mildness of the disease in all the cases under study, as evidenced by the temperature curve, as well as by the subjective symptoms, would hardly lead one to make a urinary analysis in the usual routine of practice. In fact, scarcely one of these cases would have sought professional aid in civil life. Does the evidence of the action of the disease on the kidneys shown by this study suggest an explanation for the gravity of these cases of influenza in older people, and in those afflicted with chronic disease?"

Surgeon Millard H. Crawford reports the finding of the estivo-autumnal parasite in ten cases out of forty-one of apparent influenza. These cases were clinically distinguishable by evidence of cerebral congestion, cyanosis, abortive chills, slight fever, and the disappearance of the bronchitis almost immediately upon the administration of quinine.

PURE UREA IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

Some months ago mention was made editorially in the Medical Record of a series of papers contributed by Dr. H. Harper to the *Lancet*, stating that "urea exerted a specific action on tuberculosis." Dr. Harper had given the treatment a lengthy trial with good results, and gave his reasons why urea should act beneficially on those suffering from tuberculosis. The publication of these articles aroused much attention, and several medical men have tried this treatment for consumption.

In the *Lancet*, November 22, Mr. S. Vere Pearson, medical registrar of St. George's Hospital, London, has published a paper in which he details the results gained from the treatment of seven cases of pulmonary tuberculosis by urea at the Brompton Hospital for Consumption These patients were given urea in quantities varying from five ounces to seventeen ounces during a period of from one month to fifty-eight days.

The conclusions arrived at from a study of the seven cases were based upon a comparison of the progress made by these patients with the average progress made by similar patients in the Brompton Hospital. There were taken for comparison the first 100 patients over twelve years of age with undoubted pulmonary tuberculosis, seventy-five males and twenty-five females. Of these, nine died, seventeen lost weight, seven remained stationary in weight, and the rest gained weight varying in amount from one and a half pounds to twenty-three pounds. The average alteration in weight was a gain of six and one-quarter pounds. Among those who gained weight, the majority showed improvement in physical signs as well as in general condition. Not only this, but, in the great majority, the temperature and pulse improved, and the expectoration diminished. The patients usually stayed about three months in hospital.

Of the seven patients given urea, one died. The average gain in weight was four and a half pounds, and the average length of stay was three months. Some of them improved in general condition, but in none did the physical signs show any appreciable improvement, and in several cases there was extension of disease as shown by physical signs. Urea appeared to exert no special influence upon either the pulse or temperature, and in no case was there any marked diminution in the quantity. or any appreciable improvement in the quality of the expectoration.

The amount of urea given these patients was not quite so large as the quantity sometimes employed by Dr. Harper, but Mr. Pearson is of the opinion that if urea exerts a specific action on tuberculosis, that action should make itself evident within two months when fairly large doses are being taken regularly. The conclusions arrived at from a study of these cases do not, of course, exclude the possibility that urea acts beneficially in cases of tuberculosis other than pulmonary, such, for example, as glandular tuberculosis and lupus, two varieties specified by previous users of this drug. But, so far as it is possible to judge from the results obtained in the above cases, the conclusion is that, in chronic pulmonary tuberculosis, there is no special action exerted by pure urea. It appears to exert no influence either in arresting the ravages of the disease in the lung, or in counteracting the deleterious effect upon the constitution.

Mr. Pearson summarizes the therapeutic action of urea as a result of his experience in testing the drug on persons suffering from tuberculosis as follows: (1) Urea given by the mouth in patients with chronic pulmonary tuberculosis increases the output of urea, but the total increase in this output does not, as a rule, equal the total quantity administered. (2) Urea acts only to a slight extent as a diurectic; this action is variable, and, on the whole, untrustworthy. (3) In both the output of urea and in the output of urine the effect produced by the administration of urea is more marked at first. After a time the body seems to accustom itself to the intake of urea and tends to return to its normal output. (4) Urea does not act as a cardiac stimulant.

The experiments of Mr. Pearson with urea in pulmonary tuberculosis disprove the conclusions reached by Dr. Harper. With the exception that the doses of the remedy given by the former were not so large as those administered by the latter, the investigations carried out at Brompton Hospital would seem to have been conducted in a thorough manner. Perhaps the number of patients to whom urea was given was too small to warrant the passing of any authoritative opinion on the matter, yet at the same time the experiments were conducted on a sufficiently exhaustive scale, both as regards the quantity of urea given and the number of sufferers to whom it was administered, at least to lead to the view that urea exerts no decided specific action upon pulmonary tuberculosis. Nevertheless, it must be said that the question is still an open one, and that the last word on the subject has yet to be said.

Suicide in the Russian Army.

Statistics and information concerning suicide always possess a peculiar interest for mankind at large. The subject appeals to the morbid tendency which is latent in every human being, even in the most healthy and well-balanced. and which in those of neurotic strain flourishes like the green bay tree. The fact would appear to be undoubted that suicide everywhere is on the increase. and although statistics are often untrustworthy, yet in the case of suicide they are based upon the solid foundation of truth.

In the *Voyenno Meditsinski Jurnal*, August B. Makarow writes on suicide in the Russian Army, and a part of his article is quoted in the *Lancet* of November 22.

In the period between the beginning of 1895 and the end of 1899, 238 officers of the Russian Army committed suicide or attempted to do so, the average rate per annum per 1,000 of strength having been 0.96; 214 cases occurred in the combatant branch and twenty-four among non-combatants, including seventeen members of the medical department. Among the combatants there were one general, seven senior officers, and 206 subalterns. In the Cossack regiments the suicide rate was very high, averaging 2.31 per 1,000 per annum during the five years. Contrary to what might have been expected, the rates in Siberia were comparatively low, especially in the Omsk command; while in that of Irkutsk not a single case of suicide among officers was reported during the quinquennium, 87.4 per cent. of the suicidal officers put an end to themselves with firearms, 4.6 per cent. with poison, 3.4 per cent. cut their throats, 2.1 per cent.

hanged themselves, 1.7 per cent. threw themselves from windows, and 0.8 per cent. were crushed to death by trains. Apparently drowning was not responsible for any of the fatalities.

According to the author of the article, the means selected by the suicides were those with which they were specially familiar. Thus the combatants used firearms or cold steel, the medical men poison, while the engineers, who were, for the most part, members of the railway corps, threw themselves before engines.

Among the men the cases of self-destruction were, comparatively speaking, far less numerous than among their commanders, the total number of suicides, or attempted suicides in the non-commissioned grades during the five years having been 737, which gives a rate of 0.14 per 1,000 per annum, or less than one-seventh of officers' rate. A considerable amount of space is devoted by the writer to a minute analysis of the motives which induced the suicides, officers and men, to take their lives. In many instances it was impossible to assign a plausible reason, but in the officers' category the etiology of 125 cases is said to be well established. In a table referring to these, the causes that induced the fatal act are grouped as follows: Mental disease due to syphilis or alcohol, 32 per cent.; the abuse of alcoholic beverages, 28 per cent.; love, 12.8 per cent.; family affairs, 8 per cent.; professional disappointment, 8 per cent., and gambling, 4.8 per cent.

In France, Belgium, and Russia, according to the author, suicide occurs three times as frequently in the army as in civil life. In Germany, Austria and Italy, however, the ratio is as seven or eight to one. In all armies suicide is relatively far more frequent among officers than among the rank and file. In the Austrian army the suicide rate among non-commissioned officers and men is 1.49 per 1,000 per annum, in Germany the corresponding ratio is 0.65, in France, 0.26, and in Russia, 0.14.

There are some points in the foregoing figures worthy of notice. The first of which is that the rate of suicide in the Russian army is less than in any of the other large European armies. One would be inclined to imagine that, on the whole, the lot of the Russian soldier is so much worse than that of his European compatriots, that he would be more often inclined to seek relief in death. Perhaps, his ignorance saves him from the suicidal tendency, for it is almost invariably to be observed that the majority of cases of self-destruction occur among those who are educated and frequently well endowed with brain power.

Another noteworthy point to be gathered from the statistics given above, is that the suicidal impulse is much more strongly developed in officers than in the ordinary soldiers. This, however, may be explained by the fact that the officers are better educated and, as a rule, of a more sensitive emotional type than the rank and file, in addition to which the former have more opportunities of indulging in dissipation, a potent cause of suicide.

THE ROMANCE AND HUMOR OF MEDICINE.

An article on this subject appears in the English weekly, *Public Opinion* of October 24. The romantic undoubtedly enters more intimately into the professional life of a physician than into that of any other profession. The doctor is probably the recipient of more secrets, and obtains, by virtue of his calling, more intimate insight into human character than does any other class of men. His experience is world-wide, and the tragic and the pathetic are constantly being brought to his notice. But although the busy medical practitioner is frequently confronted with grave and serious matters, the humorous side of life not uncommonly presents itself. Some few years ago, according to *Public Opinion*, a writer declared that he knew a medical man whose duty it was to take luncheon every day at a great castle belonging to a noble lord. "The household is immense," said the writer, "and there is just the chance that there may be some case of indisposition demanding attention. He gets some of the best company and best lunches in England, and duly charges a guinea ($5) for each attendance." Quite the oddest arrangement surely ever entered into was the following cited by another writer: "A medical man had been attending a patient several years, and yet has never seen the patient. The gentleman in question firmly believes he has an œsophagus of peculiar construction and that he is, accordingly, liable at any moment to be choked. That help may be at hand whenever any sudden emergency may occur, he has a physician in the house night and day. The physician, being human, must take his walks abroad, and it becomes necessary to provide a substitute for him for two hours a day. Accordingly, a doctor attends daily from twelve to two, fills up his time by disposing of an admirable lunch, and finds his fee, placed by the side of his plate, neatly wrapped in tissue paper. Up to the present date he has never had the pleasure of exchanging words with his interesting patient." Amusing in another way, and suggestive of the effect which the mind has on bodily ills, is a story related half a century or more ago of Dr. Beddoes, who, believing that nitrous oxide was a specific for paralysis, arranged to make an experiment. "Previous to the administration of the gas," we are told, "he inserted a small pocket thermometer under the tongue of the patient, to ascertain the temperature. The paralytic man, wholly ignorant of the nature of the process to which he was to submit, but deeply impressed, from the representation of Dr. Beddoes, with the certainty of success, no sooner felt the thermometer under his tongue than he concluded the talisman was in full operation, and in a burst of enthusiasm declared that he already experienced the effect of its benign influence throughout his whole body." The worthy doctor saw what had happened, abandoned his experiment, so far as this particular patient was concerned, refrained from disillusioning him, and told him to come the next day, when the thermometer was again placed under his tongue. In two weeks' time the man went away perfectly well, the cure having been effected entirely as the result of faith.

WITH REGARD TO CONSTIPATION.

There are certain people—and their number is by no means small—who if they do not have a relief from the bowels every day, at about the same time, promptly fly to an aperient to produce the desired action. With some this dependence upon aperients becomes so much a matter of routine that they may be said to have acquired the aperient habit, and they are unable—or imagine that they are unable—to retain their health without using these means of assisting nature. It is unnecessary here to inveigh against this custom in all civilized countries of the world, and especially in America.

Dr. J. F. Goodhart, in the *Lancet*, November 8, makes some excellent clinical remarks on constipation. Concerning its treatment he says that while pills undoubtedly do fill a place in the scheme of treatment, he questions whether some, at any rate, of the advantages claimed for purges do not rest upon insufficient evidence. For example, the subject of a bilious attack or migraine takes a pill and obtains relief. The pill may be said to have cured the headache, but with equal probability it can be maintained that it has only relieved a symptom and not cured the disease.

Dr. Goodhart further remarks, "When any one tells me that he can cure his headache by a dose of calomel and says that it is all stomach and only wants more care in diet and a good clear out, I say: 'You have illustrated upon the corpus vile a widely acting and important physiological principle; you have robbed Peter to pay Paul, or, rather, you have so scourged your bowels that your head forgot its own affliction in its concern for the brutal treatment that had been meted out to its minister. You draw the nervous energy from the head to the stomach and intestine and thus the headache collapses.'"

Dr. Goodhart sums up thus: "My idea, therefore, as regards aperients is that they are not harmless, as many seem to imagine, that they are much too frequently resorted to and with far too little attempt at discrimination between cases, and that there is no widely-spread recognition of the fact, notwithstanding that we are constantly administering nutrient enemata, that the colon is a great feeding organ worthy of respect and of gentle dealing."

There are certain cases in which aperients assuredly are necessary, but, in perhaps the majority of instances, the person would in the long run enjoy far better health if he foreswore such drugs, and instead would regulate his diet, take more exercise and generally lead a life less calculated to place the strain on the digestive organs which does not permit them to fulfil their functions in a proper manner.

TYPHOID FEVER AND SEWAGE DISPOSAL IN INDIA.

In the *Journal of Hygiene*, July, 1902, Major A. R. Aldridge, R.A.M.C., Sanitary Officer, Bengal Army, writes on the above subject. He commences his article by saying that although many epidemics of typhoid fever have been caused by contamination of central water supplies, it is difficult to attribute its widespread prevalence in endemic form in India and elsewhere to this cause. It is necessary, however, to guard against assuming that therefore the disease is not water borne. There are in India innumerable chances of water when stored for domestic use being contaminated, and, when it is claimed that dust or flies play an important rôle in its dissemination, it is not necessary to assume that the bacillus is taken into the mouth or respiratory passages directly, but rather that it is conveyed to water by means of dust or flies.

In India, according to Major Aldridge, most of the cases of typhoid fever among soldiers occur in stations situated in the dry, dusty alluvial plains of upper India, where the climate is generally dry and the rainfall slight throughout the year. The dry earth system of latrines and the trench system afford an excellent opportunity for the urine and fæces of those who have suffered from typhoid to contaminate the soil, and consequently the means are at hand for dust and flies to disseminate the disease indirectly by conveying its germs to stored water and food. Nearly all recent campaigns have been in dusty countries, and in these typhoid fever has been very prevalent.

The following precautionary measures are recommended by Major Aldridge: 1. Avoidance as far as possible of storage of water near habitations where, from the proximity of dry earth latrines and the filth trenches, it may be polluted. 2. Latrines and urinals should be situated as far as praticable from kitchens and stored water. They should have impervious floors. 3. All food, feeding utensils, etc., should be protected from dust and flies. 4. It is recommended that a trial be made in some cantonment which has suffered much from enteric fever of any form of water carriage of sewage. 5. For sewage disposal Major Aldridge recommends one of the bacterial methods, with application of the effluent to the land.

THE PHYSIOLOGY OF THE VIOLET LIGHT.

Light has of late years come prominently to the front as a remedial curative agent. Of course, it has been known from time immemorial that light was conducive to health, but it is only recently that the full force of this truth has been definitely recognized. Light is the most potent factor in the successful treatment of tuberculosis, and it is beneficial to a greater or less extent in almost all diseases. The discovery that the *x*-rays and the Finsen light have a remarkable healing effect upon certain skin diseases and even upon cancer has opened so vast a field of investigation that its scope may almost be said to be boundless. Research in this respect is but in its infancy, and he would be a bold man to assert that the limits of the light treatment can be defined.

Dr. James Weir, Jr., writing in the *Scientific American*, November 22, says the following concerning the violet rays:

"The violet rays are absolutely necessary in the upbuilding of the normal healthy man. Their action must be, I take it, primarily through stimulation of the vasomotor nerves. The first effect is dynamic in character; there is dilation of the blood vessels with a consequent increased flow of blood. The second effect is chemical in nature; the increased flow of blood incites the blood-producing organs to manufacture new blood cells. Consequently the plasma of these cells differs chemically from the plasma of the old cells. There is also increased oxidation and oxygenation through the lungs. The third effect is purely physiological. Owing to the increased flow of new blood cells to the tissues, cell growth is excited and new tissue is formed. Of course, waste is going on all the time; the violet rays merely act as a tonic in stimulating the organs of the animal economy toward repairment of waste by removing and building up tissue. These beneficial rays are present in diffused daylight, hence the direct rays of the sun are not absolutely necessary in order to produce their good effects on the animal organism. Direct sunlight is, however, an exceedingly efficacious tonic when used moderately and understandingly; there can be intemperance, however, in the use of every good thing that nature has given us."

Fresh Denials from San Francisco.—A press correspondent in San Francisco is responsible for the story that Dr. Glennon of the Public Health and Marine Hospital Service is preparing a report to Surgeon-General Wyman to the effect that there had never been bubonic plague in California. Dr. Glennon will, it is asserted, declare positively that, after a thorough and exhaustive investigation, he has decided that the bacillus supposed to be that of plague is that of chicken cholera. His conclusions, if correctly stated, bear out the diagnosis made by the newspaper editors and politicians of San Francisco, who have consistently and persistently declared that the Marine-Hospital experts and others are all wrong in asserting that any cases of plague have occurred in that city.

News of the Week.

Dr. Bulkley's Lectures on Diseases of the Skin.—The governors of the New York Skin and Cancer Hospital, Second Avenue, corner of Nineteenth Street, announce that Dr. L. Duncan Bulkley will give his fifth series of clinical lectures on "Diseases of the Skin" in the out-patient hall of the hospital on Wednesday afternoons, commencing January 7, 1903, at 4.15 o'clock. The course will be free to the medical profession. This interesting and popular course of lectures begins later this year than heretofore, the opening clinic in former years having always been held on the first Wednesday in November.

Cholera in the Philippines.—It is reported that cholera has broken out afresh at Manila, some thirty cases of the disease being reported daily. In the southern provinces it is present in epidemic form, and at Iloilo the death rate is very heavy, the authorities seeming to be powerless to check the spread of the disease.

The Eastern Medical Society of New York.—At a meeting of the Eastern Medical Society, held on Friday evening, December 12, 1902, the following officers were elected: *President*, Louis J. Ladinski; *First Vice-President*, E. K. Brown; *Second Vice-President*, A. Hymanson; *Secretary*, Albert Miller; *Treasurer*, Bernard Gordon; *Chairman Committee on Ways and Means*, David Robinsohn; *Chairman Committee on Ethics*, Simon Marx; *Trustee*, A. E. Isaacs; *Committee on Admission*, Charles Goodman, *Chairman*; M. Wolper, M. Rabinovitz, J. Heller, M. Frankel.

Dr. William M. Leszynsky has been appointed neurologist to the Lebanon Hospital of this city.

Plague on Swinburne Island.—Three men suffering from plague arrived in this port on December 15, from South Africa, and were taken to the quarantine hospital on Swinburne Island. The steamer which brought the men was fumigated and disinfected.

Charter for a Tuberculosis Congress.—A petition was filed in the Superior Court of Georgia at Atlanta on December 17, asking for a charter for the incorporation of the "American Congress on Tuberculosis." The purpose of the corporation is stated to be to promote discussion and devise means of bettering the condition of patients suffering with tuberculosis. Another object is to assist in organizing the world's congress on tuberculosis.

Extinction by Disease of a Once-Powerful Indian Tribe.—Dr. Wyman, Government physician at the Sac and Fox Indian Agency, in Oklahoma, announces that a large majority of the tribe are afflicted with tuberculosis, scrofula, and other incurable diseases, and adds that the tribe will be extinct within a few years. The latest census gives the number of members of the tribe as only 479.

Centenary of the New Haven Medical Association.—The New Haven Medical Association of New Haven, Conn., will celebrate the one hundredth anniversary of its organization on Monday and Tuesday, January 5 and 6, 1903. Commemorative addresses will be delivered on Tuesday afternoon by Dr. William Osler of Baltimore and Dr. Francis Bacon of New Haven in the auditorium of the New Haven Colony Historical Society. A reception in honor of Dr. Osler and Dr. Bacon will be given on Monday evening at the Yale School of the Fine Arts. The annual dinner of the association will be held on Tuesday evening. The committee in charge of the arrangements consists of Dr. Gustavus Eliot, Dr. Henry Lawrence Swain, and Dr. Ralph Schuyler Goodwin, Jr.

Unauthorized Use of a Physician's Name.—Dr. Egbert H. Grandin of this city writes to protest against the use, by the manufacturer of a proprietary preparation, of a general therapeutic statement attributed to him and seeming to imply an endorsement of the special preparation. Dr. Grandin writes: "Since I have uniformly declined to vouch for anything of a patent or proprietary nature during the many years I have practised my profession, will you oblige me by publishing this—an emphatic protest—against what may be mildly termed illegitimate, unbusinesslike methods."

Dangers of the Lorenz Method.—That "bloodless surgery" is not without its accidents has been abundantly demonstrated during the visit of the Vienna orthopedist to this country. In an editorial article in the *Journal of the American Medical Association* it is stated that even in the few cases operated on by Lorenz during his stay in Chicago—and they were cases carefully selected from a large amount of material—there was one case of fracture of the femur, one of extensive hæmatoma, and one of complete laceration of the perineum extending from the vagina into the rectum.

Licensed Optometry.—The opticians of this State propose to make another effort to induce the Legislature to create a board of examiners in optometry, without a license from which it shall be illegal to practise optometry. This is defined as "the employment of subjective and objective mechanical means to determine the accommodative and refractive states of the eye, and the scope of its functions in general, or the act of adapting glasses to the eye by using such skilled means as will determine their choice." Physicians duly licensed to practise medicine in the State are to be exempt from the provisions of the proposed act. Others who practise optometry without a license will be adjudged guilty of a misdemeanor.

An International Quarantine League.—As a result of the recent meeting of the American Public Health Association at New Orleans, the International Quarantine League has been formed with Dr. J. M. Lindsay as president, and a membership of 150 medical men of the United States, Cuba, Mexico, and South America. The league accepts the doctrine that the mosquito is the only means by which yellow fever is transmitted, and that the proper protection against an epidemic of yellow fever is the destruction of mosquitos or preventing them from gaining access to persons ill with the fever. The object of the league is to secure a modification of quarantine against yellow fever, in conformity with the resolutions adopted by the International Sanitary Congress at Havana last February.

War against Tuberculosis in Paris.—The *Figaro* of Paris recently opened a subscription for the establishment of a sanatorium for consumption at Bligny and of a system of dispensaries in Paris, and has already raised by this means about 350,000 francs.

The X-Ray as a Thief Catcher.—It is said that many employees of the Japanese mint are in the habit of increasing their wages by swallowing occasionally one of the newly-minted coins and recovering the same later in the privacy of their homes. In order to circumvent this practice the officials of the mint have set up an *x*-ray detective, and the employees will be occasionally skiagraphed before leaving the mint.

A Physician and His Bill.—During the trial of a suit for damages brought by a woman against the Brooklyn Rapid Transit Company, about ten days ago, a physician, who had treated the injured plaintiff, was called as a witness for the defense. According to the testimony he gave, he visited the woman three times a day for three weeks, although he did not think there was much the matter with her.

On being asked why, then, he visited her so often he admitted that he did so in order to increase the size of his bill, and said that for his unnecessary services he sent in a bill of $120. The plaintiff, in spite of her medical attendant's testimony, was awarded $7,750 by a jury.

Naval Dentists.—A hearing on dentistry was given at Washington on December 13 by the House Committee on Naval Affairs, and many leading dentists were present to urge that a bill be passed raising the grade of naval dentists. At present they are rated as yeomen, but the National Dental Association wants a "Dental Corps" created so that the dentists may have proper rank and pay.

The Late Dr. Daniel P. Pease.—At a meeting of the City (Charity) Hospital Alumni Society, held December 10, 1902, a committee appointed by the President drew up the following resolutions, which were passed:

Whereas, In the death of Dr. Daniel P. Pease, this Society has lost an old and valued member, who served it long and well,

Be it Resolved, That this Society express its regrets at his untimely death; and further be it

Resolved, That the following obituary, together with these resolutions, be recorded in the Society's minutes, and sent to the Medical Press.

Dr. Daniel Pearson Pease was born forty-five years ago in Chicopee, Mass., He was graduated from Bellevue Hospital Medical College in 1882. He was interne at Charity Hospital, leaving in 1883. For many years he was with the Board of Health at Riverside and North Brothers Island Hospitals, and later as expert diagnostician. He was one of the early members of the City (Charity) Hospital Alumni Society, and always active in its interests. He was a member of the County Society, Academy of Medicine and Physicians' Mutual Aid Society. Of late years he had been especially identified with the practice of the Hoffman House, Albemarle, and Fifth Avenue Hotels. His genial ways made for him many friends at home and abroad, for he was fond of travel. While in Holland last summer he became ill, and hastened to Paris. There he went to a private hospital, where he suffered eight weeks with typhoid fever and its complications. An intestinal perforation caused his death, December 7, 1902. He was a man of sterling qualities, firm in his convictions, true to his friends, and faithful to his duty. He was a man always to be relied upon, tireless, energetic, and with all the qualifications which go to make up the successful and able physician and the broad-minded and kindly gentleman. Dr. Pease was a bachelor. While he leaves no family, he does leave a host of friends, both in and out of the profession, who will ever keep him in pleasant memory.

Joseph B. Bissell, *Chairman*,
W. L. Stowell,
W. L. Baner.

Mother Eddy on Vaccination.—Mother Mary Baker Eddy of Christian Science notoriety, having been asked by certain disciples what should be done when the ungodly insist upon vaccinating them and their children, returned the wise and canny answer herewith: "Rather than quarrel over vaccination I recommend that if the law demands an individual to submit to this process he obey the law and then appeal to the gospel to save him from any bad result. When Jesus was questioned about obeying the human law, he declared, 'Render unto Cæsar the things that are Cæsar's even while you render unto God the things that are God's.'"

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

GENERAL MEDICAL COUNCIL—THROMBOSIS IN TYPHOID FEVER—RUPTURED CRUCIAL LIGAMENTS—HEPATIC ABSCESS—DANGERS OF THE TAXIS IN HERNIA—ASYLUMS BOARD—BACTERIAL TREATMENT OF SEWAGE—PUNISHMENT FOR ENURESIS.

London, December 5, 1902

The remainder of the proceedings of the General Medical Council will have very little interest for you. New rules were adopted for the prevention of personation. The credit of bringing this matter to a satisfactory conclusion was accorded by the president to Sir Victor Horsley, who is one of the most active councillors. He called the English colleges to account by a question as to why they had sent no reply to the report of the inspection of their primary examination. The representatives of these colleges made excuses to the effect that they required more time to do so—a rather unreasonable answer, considering that hundreds of copies have been circulated.

The report on financial relations was once more discussed at length, and eventually, once more postponed. A draft bill, to be brought before Parliament, with a view of effecting such changes as would prevent a financial catastrophy, gave rise to many differences of opinion. Some thought severe economies would arrest the progress toward bankruptcy; others held that they could not save by them the £1,500 a year required, and that the fee for registration must be increased, and a fee exacted from students, with compulsory registration. Another proposal, called a "major economy," was that the fees of councillors should be reduced from five guineas per day's attendance to three, or two, or even to *nil*.

If the council is to consist of eminent specialists and leaders of the profession, five guineas is only an *honorarium*, and attendance to many involves loss. On the other hand, most of these eminent gentlemen are not authorities on the state of the profession—its wants, its struggles, and the need of reforms. Their services are really rendered to their several corporations, rather than to the profession. Then let the corporations pay them, until we can accomplish a drastic reform of the constitution of the council. It is a very unwieldy body, ill-adapted to discharge judicial functions. It manages to perform its penal duties with impartiality, though at an enormous cost. It seems a *reductio ad absurdum* to bring distinguished physicians and surgeons from all parts of the Kingdom to decide if some men have acted in a manner "infamous in a professional respect." So, too, the keeping of the register is a work which could be done better by a small body. These and other considerations point distinctly to the necessity of reducing the numbers of the councillors sufficiently to make it a body capable of transacting its business at a moderate expense, and in a business-like manner.

Thrombosis occurring in typhoid fever was the subject of an interesting paper submitted to the Medico-Chirurgical Society by Professor Wright and Dr. H. H. G. Knapp. Their research had special reference to the influence of lime salts in the blood. They found that the coagulation time varied in the normal adult, male, between three and one-half and fifteen minutes. In the acute stage of typhoid fever they found diminished coagulability, in convalescents the reverse. The average calcium salts in convalescents was about double that in normal blood. To prevent deposit of fibrin, the blood coagulability could be diminished by a decalcifying drug, *e.g.* citric acid. The thrombosis which so often occurs in connection with typhoid fever might be due to excess of calcium salts in the blood of convalescents, and it was suggested that this excess was derived from the milk of the diet. Cow's milk contains one part of CaO in 600, while lime water only contains 1 in 800. If the generally almost exclusive milk diet, adopted in typhoid fever, accounted for the frequency of thrombosis during convalescence, a clue was furnished to other problems, such as the benefit of milk diet in "serous hemorrhage" from the kidneys, and the comparative rarity of thrombosis after other acute fevers in which a milk diet was not usually employed. So citric acid might be given as a preventive as soon as the danger of intestinal hemorrhage was passed. Or, as an alternative, the milk might be decalcified by adding to it 0.25 to 0.5 per cent. of sodium citrate.

Dr. Wm. Hunter congratulated the authors of this paper, and said he had been in the habit of giving citrate of soda in febrile conditions with benefit, and their research gave the practice a scientific explanation.

Dr. Rolleston referred to the excessive frequency of thrombosis observed in South Africa, and thought it due to decreased resistance caused by the over-exertion of the lower limbs in constant marching, though the late Dr. Washbourn attributed it to tinned food diet, while the usual opinion referred it to infection of the vein walls by the typhoid bacilli. He admitted the possibility of the tinned milk being the cause of increased coagulability.

Dr. Newton Pitt said organisms had been found in the thrombi, and remarked that infants fed on milk did not suffer from thrombosis.

Dr. Ogle suggested that citric acid might possibly loosen the clot and cause embolism.

Dr. Wright, in reply, had met no sign of this, admitted bacteria might be one factor, and only claimed that lime salts were also one. It was not known if children absorbed the lime, and it was known that their coagulability was low. The amount of lime in milk diet was more than enough to account for the excess in the blood, and condensed milk was presumably richer in lime.

The Clinical Society had a surgical evening on Friday. Mr. Mayo Robson read an account of a case of ruptured crucial ligaments, the result of a mining accident causing this and numerous other injuries by a fall of earth, which almost buried the patient. He opened the joint and found both crucial ligaments had been torn from their upper attachments, the ends being in a shreddy state. He stitched them in position with catgut ligatures—the anterior to the synovial membrane and tissues on the inner side of the external condyle, the posterior to the membrane and cartilage on the outer side of the inner condyle; the latter, being too short, was split to lengthen it. The wound was stitched up by buried catgut sutures, and closed superficially by interrupted silk-worm sutures. The case was very successful, complete restoration of the joint movements being obtained.

Mr. Marsh (president) said that strong non-vascular tissues had been ruptured in such a way. He would avoid opening a joint when inflamed. He had seen a case in which the knee was in a flail-like condition, but six months later had become fairly serviceable.

Mr. Spencer doubted if the attachment by scar tissue would be strong enough if the ligaments were completely ruptured. Sometimes a plate of bone was torn away.

Mr. Robson, in reply, agreed with the general view to avoid operating on inflamed joints. In his case the limb was quite useless nine months after the accident, and the only alternative was amputation.

Lieutenant-Colonel W. K. Hatch, I.M.S., then read a paper on hepatic abscess, of which he had seen upward of 1,000 cases in India. It was very common among the natives. Alcohol was one cause, but the majority had had dysentery. He insisted on a strong hepatic odor from the patient as a diagnostic point, and described the other signs. The main object of the paper, however, was to call attention to the danger of aspiration, which ought only to be resorted to when the diagnosis was established to fix the exact locality of the abscess. There was great danger in puncturing an enlarged, highly congested liver, as there must also be of wounding a large hepatic vessel. The vena cava might even be touched with fatal result. His practice was to open the abdomen by a two-inch incision, and expose the liver. Then a cannula could be introduced more safely. He deprecated excision of ribs. He never irrigated an abscess unless it became septic.

Mr. Marsh did not attach much importance to cutting into the abscess through the peritoneum, although it was usually thought risky. He preferred to expose the abscess, pack gauze all around the presenting part, so that adhesions might form in a day or two, and shut off the peritoneal cavity.

Mr. Bowlby thought it best; when hepatic abscesses were attacked through the pleura to shut off that cavity; although it was said the pus was sterile it would not if remain so long.

Mr. Robeson agreed with Colonel Hatch as to the risks of the indiscriminate blind exploration, so widely practised. He hoped exploration of suspected distended gall-bladder was a thing of the past. In hepatic abscess it was safer to open the abdomen, see what one was doing, and arrest hemorrhage, if it occurred.

After some further discussion on this subject, Mr. Lawrie McGavin read notes of a case of strangulated hernia with *réduction en masse*, and proceeded to insist on the dangers of the taxis. He held that, in view of the disasters which have occurred, it is time to abandon taxis as an empirical measure, unworthy of the name of surgery, which exposes the patient to risks of which he knows nothing, and from which the surgeon ought to safeguard him. He reviewed these several risks, and expressed his wonder that any surgeon would be willing to face them, for all were serious, many cases are by taxis rendered nearly hopeless, and the mortality is always high. In the discussion which followed this paper the surgeons recognized the risks of taxis, and one said he had forbidden it in his hospital for twenty years. Others held that, in certain cases strictly limited, it was useful, and one said, if altogether abandoned, some lives might be lost.

The Asylums Board has made inquiries among the local authorities as to their views on a proposal that the treatment of consumption should be undertaken by the board. Out of twenty-six borough councils, ten approved, five favored the open-air plan, but were not agreed as to what authority should undertake it, the other eleven had either given no opinion or were adverse to the proposal. In consequence of the differences of opinion, the further consideration of the subject has been adjourned for twelve months.

The experiments on the bacterial treatment of crude sewage at the county councils' outfalls have been discontinued for the present, and a further report to the council by Professor Clowes has been issued. This report gives a brief statement of the nature and results of the experiments, and the conclusions toward which they point. It says that the bacterial effluent of settled sewage from the coke-beds undergoes no offensive putrifaction, even in summer heat; it cannot become offensive; it supports the respiration of fish. When this treatment is applied the use of chemicals is never necessary. To apply it to the London sewage the necessary works will take time to construct, but if done without delay the increasing deterioration of the lower Thames will be checked and ultimately prevented. The gradual development of the treatment will cause the considerable cost be spread over several years.

We have had a sensation trial of a well-to-do mother, wife of a magistrate, for cruelty to her daughter, a child between six and seven years of age. The defence was that the acts of cruelty alleged, some of which were of an astonishing character, were all chastisements administered to cure the child of "a bad habit," nocturnal enuresis. The society for preventing cruelty to children prosecuted at the instigation of servants, who had been dismissed, or had left, some before and others, it was said, after giving the information. Some of the "punishments" or "cruelties" really amounted to torture, and it is amazing that an educated woman and her husband should have believed it possible to cure the child thus. Pity for the poor little girl produced indignation throughout the neighborhood, and the trial was removed to London. The verdict was guilty, and a fine of £50 imposed, whereupon sensation papers raised the cry that there is one law for the rich, another for the poor, ignoring the fact that the judge took that course because he said he believed the excess in the punishments was due to temper rather than intentional cruelty.

The papers in question are certainly unjust in omitting or obscuring the "infirmity" put forth as a defence, for it is a fact that a widely-diffused opinion prevails that enuresis is amenable to punishment, which is accordingly too often administered by ignorant persons instead of consulting a doctor.

Many a child has suffered for years from this cause, the malady being really aggravated by the treatment, the moral effect of which is most deplorable. It may be hoped that the publicity given to this case will go far to explode the belief that has caused great suffering, and is so general that it was confidently put forward by eminent counsel as a sufficient excuse for almost incredible acts.

If the newspapers had used the occasion to enforce the folly of the superstition instead of criticising the judge they might have done much good.

A DECLARATION AGAINST ALCOHOL.

To the Editor of the Medical Record:

Sir: Will you be kind enough to publish in your excellent journal the following statements and appeal to the medical profession of the country? During the last half century the medical profession in Europe and this country have made three distinct declarations concerning the nature and effects of alcohol on the body. The first appeared in 1839, and was signed by only seventy-eight physicians. It was a public statement affirming that alcohol as a food and beverage was injurious, and should not be used in this way. The second declaration appeared in 1847, and declared, among other things, that alcohol was not needed in health, and that total abstinence gave the strongest promise of longevity. This declaration was signed by 2,000 physicians in Great Britain, on the continent, and in this country. The third declaration appeared in 1871, and while reaffirming the statements of the former manifestos, declared alcohol to be a poison and powerful drug that should only be used by physicians with care and caution. This was signed by over 4,000 physicians, including many of the leading physicians in every part of the world. A fourth manifesto or declaration of opinions has been projected, and is now being circulated for signatures among leading physicians in every civilized country. The following is the text of this declaration:

"The purpose of this is to have a general agreement of opinions of all prominent physicians in civilized countries concerning the dangers from alcohol, and in this way give support to the efforts made to check and prevent the evils from this source. In view of the terrible evils which have resulted from the consumption of alcohols, evils which in many parts of the world are rapidly increasing, we, members of the medical profession, feel it to be our duty, as being in some sense the guardians of the public health, to speak plainly of the nature of alcohol, and of the injury to the individual and the danger to the community which arise from the prevalent use of intoxicating liquors as beverages. We think it ought to be known by all that: (1) Experiments have demonstrated that even a small quantity of alcoholic liquor, either immediately or after a short time, prevents perfect mental action, and interferes with the functions of the cells and tissues of the body, impairing self control by producing progressive paralysis of the judgment and of the will; and having other markedly injurious effects. Hence, alcohol must be regarded as a poison, and ought not to be classed among foods (2) Observation establishes the fact that a moderate use of alcoholic liquors, continued over a number of years, produces a gradual deterioration of the tissues of the body, and hastens the changes which old age brings, thus increasing the average liability to disease (especially to infectious disease), and shortening the duration of life. (3) Total abstainers, other conditions being similar, can perform more work, possess greater powers of endurance, have on the average less sickness, and recover more quickly than non-abstainers, especially from infectious diseases, while they altogether escape diseases specially caused by alcohol. (4) All the bodily functions of a man, as of every other animal, are best performed in the absence of alcohol, and any supposed experience to the contrary is founded on delusion, a result of the action of alcohol on the nerve centers. (5) Further, alcohol tends to produce in the offspring of drinkers an unstable nervous system, lowering them mentally, morally, and physically. Thus, deterioration of the race threatens us, and this is likely to be greatly accelerated by the alarming increase of drinking among women, who have hitherto been little addicted to this vice. Since the mothers of the coming generation are thus involved, the importance and danger of this increase cannot be exaggerated. Seeing, then, that the common use of alcoholic beverages is always and everywhere followed, sooner or later, by moral, physical, and social results of a most serious and threatening character, and that it is the cause, direct or indirect, of a very large proportion of the poverty, suffering, vice, crime, lunacy disease, and death, not only in the case of those who take such beverages, but in the case of others who are unavoidably associated with them, we feel warranted, nay, compelled to urge the general adoption of total abstinence from all intoxicating liquors as beverages as the surest, simplest, and quickest method of removing the evils which necessarily result from their use. Such a course is not only universally safe, but is also natural. We believe that such an era of health, happiness, and prosperity would be inaugurated thereby that many of the social problems of the present age would be solved."

This declaration has been signed by over a 1,000 physicians in Great Britain and on the continent, and promises to be one of the most authoritative statements of the judgment of leading physicians which has been made. The matter is purely a scientific one, and has grown up from a realization of the danger from the indiscriminate use of alcohol, and is given as indicating the general medical interests on this subject, and for the purpose of assisting public sentiment in the correction of one of the impending evils of the day. I have been appointed to solicit signatures from leading physicians in all sections of the country. This declaration with its signatures will be made public some time in the coming year, and its value and influence cannot be over-estimated. I should be pleased to receive the names, titles, and addresses of any physicians who are willing to assist in making this a distinct movement to correct and educate public sentiment in the right direction. American physicians should be equally enthusiastic and prompt to give their signatures to this declaration, as physicians, in the wine-drinking countries of Europe. A postal card or letter, giving the address and titles, is earnestly solicited from every physician who would like to help on this last great movement to show that the medical profession is interested in controlling one of the greatest evils of the age.

T. D. CROTHERS, M.D.

HARTFORD, CONN., December 11, 1902.

THE AMERICAN SCHOOL OF MEDICINE AT BEYROOT, SYRIA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: In your letter from Constantinople, dated October 15, 1902, I find a paragraph about the American School of Medicine at Beyroot, Syria, which is so misleading that it needs at least a word of correction. The medical department of the Syrian Protestant College has been in existence continually since 1867, and, like the collegiate department, is under the jurisdiction of the Regents of the State of New York. The course, approved by them, is a four-years-graded one, modeled on that of the College of Physicians and Surgeons of New York. The clinical instruction is obligatory, and is given daily to all the members of the two upper classes in the wards and out-patient department of the St. John's Hospital, an institution sustained by the German order of Knights of St. John, under the direction of the Kaiserswerth Sisters, and officered by the American physicians of the Medical School. No more thorough clinical instruction is given in any undergraduate medical school in Europe or America. The students see and handle over 500 cases in the wards and between 15,000 and 18,000 cases in the out-patient department annually.

The final examinations of the Medical School equal those of any first-class American medical school, and are supplemented by the New York State Regents' examinations, conducted in Beyroot by the United States Consul. In addition to this, all graduates, before practising in the Turkish Empire, are required to pass the full examination of the Imperial Ottoman Medical School at Constantinople, which they do successfully.

As in the case of so many other Orientals, some students prefer to come away from their own country, for the sake of greater freedom, and finish their studies in Europe or America, and there are numerous cases on record in which men plucked at the second or third-year examinations, have come to the United States and received an M.D. at medical schools here before their classmates in Beyroot had graduated.

The members of the Beyroot medical faculty stand second to none in prominence in their profession, and all of them are men well known and highly esteemed throughout the whole Turkish Empire, as well as in Europe and America. No better endorsement is needed of the repute in which the graduates of the American Medical School at Beyroot are held than the fact that the Turkish Government seeks them out for its most important medical positions in Asia Minor, Syria, Palestine, and Egypt.

WILLIAM GRAY SCHAUFFLER, M.D.,

Formerly for six years Professor of Physiology and Diseases of Women at the Syrian Protestant College, Beyroot, Syria.

LAKEWOOD, N. J.

TYPHOID INFECTION; A SUGGESTION.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: In August, 1901, I treated a case of typhoid fever that suggested to me a source of infection that, so far as I know, has never been suspected. The patient was a strong, healthy young women of eighteen years, who served as a clerk in a large insurance office in New York City. The disease ran a typical course, the highest temperature being 104 F°. On the carbolated-camphor treatment, she was out walking at the end of the fifth week. The case was an isolated one, and for a long time I searched in vain for the source of infection. The water she drank in the city came from a tank at the top of the building, and finally she told me that Croton bugs, or cockroaches came from the faucet rather frequently. This suggested to me that the roaches might become infected from the waste pipes, crawl into the tank, and thus infect the drinking water. I offer this as a suggestion simply, to those situated so that they are able to study the Croton bug as a carrier of typhoid infection.

D. E. ENGLISH, M.D.

MILLBURN N. J.

ALLEGED TYPHOID FEVER IN BERMUDA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: Thinking that maybe rumors of an outbreak of so-called typhoid fever may have reached your city, and, peradventure, it might have a deterring effect on prospective tourists this comingwinter, I write a few lines to state that in my opinion the disease is not typhoid fever, although I admit that doctors in the city of Hamilton have made returns to the Medical Officer of Health of upward of one hundred cases of typhoid. I have not been engaged in active practice this past summer, owing to ill health, hence I have seen but few cases of this fever. About a fortnight ago I had a case, in a boy, aged eight years. He had considerable fever, temperature, 101; pain in head, vertigo, and aching pains in limbs, and complained of tightness across the abdomen. The tongue was coated with a not very marked strawberry appearance. The patient was kept in bed for a week, and was out of doors on the tenth day. I am inclined to believe this fever came from the Boer prison islands in the great sound, as frequent communication was kept up with the camps. The disease got on shore, and has prevailed throughout the western parishes quite extensively. My friend, Dr. T. A. Outerbridge, saw and treated a case, in the person of the chaplain employed to look after the prisoners. He recovered in a fortnight's time, and returned to the islands. I do not consider this fever to be dangerous; it is, I believe, dengue, or broken-bone fever. There have been no fatal cases to my knowledge. I see no grounds for alarm. Our islands are as healthy as ever, but now and then "a small fever," as Dr. O. W. Holmes once wittily remarked, "is by our medico's thankfully received."

A. Outerbridge, M.D.

Flatts Village, Bermuda, November 27, 1902.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Dec. 18, 1902.

Cases of Typhoid Fever Simulating Puerperal Sepsis.—H. T. Swain reports three cases of typhoid fever developed immediately after labor and simulating a virulent sepsis. The sudden rise of temperature without prodromata, the sudden rise of pulse and its rapid loss of character were like sepsis; general abdominal tenderness might have been present in either disease. The diagnostic points of typhoid were the low count of leucocytes and some rose spots. The patients made a good recovery.

Eleven Acute and Eighteen Chronic Cases of Influenza.—Frederick T. Lord reports these cases (proved by bacteriological examination) and reaches the following conclusions: (1) Infection with influenza bacilli is prevalent apart from an epidemic of influenza. Influenza-bacilli have been found in the sputa of sixty of one hundred unselected cases with cough. In about one-half of these sixty cases the influenza bacilli were in practically pure culture. (2) There is nothing distinctive in the clinical manifestations of influenza apart from epidemics, and the diagnosis can with certainty be made only by the examination of the sputum for influenza bacilli. (3) The duration of the cough and expectoration after an attack of acute influenza does not usually exceed six weeks, but in some cases the duration is for months or years. (4) Many of the cases formerly classed as chronic bronchitis are chronic influenza. (5) Cases of chronic influenza with paroxysm dyspnœa may closely resemble asthma; (6) Chronic influenza is not infrequently mistaken for pulmonary tuberculosis.

Journal of the American Medical Association, Dec. 20, 1902.

Dermatitis Hiemalis.—Under this heading W. T. Corlett describes a recurrent inflammation of the skin associated with cold weather. Twelve new clinical histories are given (in addition to fourteen previously reported), and several excellent illustrations accompany the paper. The disease generally localizes itself on the backs of the hands. The author has been convinced that the affection is more closely allied to the erythemata than was at first supposed. Not only is the color suggestive of some forms of erythema, being of a dark-bluish tint, but, like erythema, it more frequently attacks the distal extremities or parts farthest removed from the center of circulation. Again, like the erythematous group, it is more frequently met in the months in which there is the greatest variability in temperature, which prevails most frequently during the early winter and the early spring months. The histologic findings show nothing distinctive, and the extent of changes in the skin seems to be wholly dependent on the amount of circulatory disturbance. That cold may be regarded as a causative factor in the affection seems to me to be well established; that the same influences are causative in the erythematous group is likewise generally accepted. He would, therefore, regard the disease as one allied to eczema, while characterized by some of the clinical features of erythema, presenting a clinical picture quite distinct, which further observation may show is to be looked upon as a disease *sui generis*. Treatment depends on the fact as to whether or not we have an excoriated area or a thick and hypertrophied condition of the skin to contend with. In the former condition some slightly astringent soothing application, such as the glycerid of tannin, diluted with distilled hamamelis (1 to 3), lead wash, or the evaporating lotion of Hutchinson (liquor plumbi ʒii, spts. rectificati ℥iii to aquæ q. s. ℥viii). When the disease has become chronic with hypertrophy, salicylic acid grs. xx, ung. diachyli ʒii. In place of the diachylon ointment, mercury or tar may be used in ointment form. In all cases the hands should be protected by wearing leather gloves, and, when practicable, a change of climate affords the most certain means of immediate relief, although it does not eradicate the tendency to the disease.

Medical News, December 20, 1902.

Rubella Scarlatinosa.—Frederick C. Curtis and Henry L. K. Shaw report an epidemic of this disease. The endemic character of the disease was striking. A majority of the patients were adults. The period of incubation averaged about nineteen days. The onset was generally sudden, and in the severe attacks was attended by feelings of malaise, headache, sore throat, slight fever, and enlargement of the lymph nodes in the region of the neck, groin, and axilla. In the milder form the rash and the enlarged glands were the only symptoms observed. There was no sneezing or redness of the conjunctiva in any of the cases. Sore throat was universally present, and was often very severe. The pulse was not rapid. No albumin in the urine was detected in any of the cases. There was some variety of cutaneous lesions. In the majority the color was bright red. There was not the punctate redness so marked in scarlet fever, and there was uniform but transient blanching on pressure instead of the prolonged blanching with red punctæ or deeply-congested papillæ characteristic of the scarlatinal rash. This is an important point. The duration of the active skin lesion was, as a rule, about a week. Not one death was attributable to this disease, with the possible exception of one, a female past seventy years, who died from possible secondary complications due to the disease. The complications and sequelæ were: rheumatism, bronchitis, pneumonia, erysipelas, erythema nodolum, acute otorrhœa, quinsy, pleurisy, cystitis, and myocarditis. Involvement of the lymphatic system was a constant manifestation of the disease, and was an important feature of the epidemic. One of the diagnostic signs of rubella is the enlargement of the lymph glands, especially those in the region of the neck.

Acute Pancreatitis, with the Report of Three Cases.—George Woolsey declares that acute inflammation of the pancreas as a condition amenable to surgical operation is not of frequent occurrence, and is rather obscure. Acute pancreatitis is one of the causes of sudden death, and, in most cases, the patient is in a more or less profound collapse at the onset of inflammation. The gland is more or less infiltrated with small hemorrhages, and more extensive ones may be found in the root of the mesentery, the retroperitoneal tissue, or the lesser peritoneal sac. It is not settled whether this hemorrhage is primary, or is secondary to the inflammation and results from it. Besides the hemorrhages, a hemorrhagic tendency, similar to that sometimes observed in cholæmia, is sometimes present in pancreatitis. Another feature of some cases of acute pancreatitis is the occurrence of fat necrosis in the subperitoneal fat. This condition is rarely met with apart from affections of the pancreas. It is not found in all acute diseases of the pancreas. Another kind of acute pancreatitis is characterized by the occurrence of necrosis of the pancreatic tissue in whole or in part. Still another variety is suppurative or purulent pancreatitis, an advanced stage of acute pancreatitis. Alcoholism is an important etiological factor, probably by causing a gastroduodenal catarrh. The inflammation of this tract predisposes to bacterial infection. As to the symptoms, there is sudden onset with more or less collapse, severe, cramp-like epigastric pain, not relieved by vomiting, distention of the abdomen, and an irregular temperature. The diagnosis is generally difficult and uncertain, on account of the number of inconstant and contradictory symptoms. As to operation, it is generally admitted that it should be avoided in the acute early stages, when the symptoms are indefinite and the patient is in collapse. The prognosis is grave in acute pancreatitis. It varies with the severity and form of the acute inflammation.

New York Medical Journal, December 20, 1902.

Laryngectomy for Malignant Disease.—The paper of F. Hartley, begun in the previous issue of the *Journal* and concluded in the present issue, reviews the various steps in the development of the present status of the operation, and is a most valuable contribution. He narrates his personal experience with five patients. Case I was a man of forty-nine years—well four years after operation. Case II, man of sixty years, well four and one-half years after operation. Case III, man of fifty years, well five years after operation. Case IV, a man of thirty-six years, recurrence in deep cervical glands fourteen months after operation, considered inoperable; death three months later. Case V, a woman of forty-one years; no recurrence ten months after operation. The author believes that statistics are much more favorable now than formerly, and calls attention to the remarkable development of a voice in some patients after a total excision of the larynx has been done. He lays special stress on the necessity of the most careful after-treatment in these cases.

American Medicine, December 20, 1902.

Failures in the Irrigation Treatment of Gonorrhœa.—Ferd. C. Valentine states that although the irrigation treatment is not an invariable panacea for gonorrhœa, still it is the most effective method known to combat this disease. In some instances irrigations fail. Some of the failures are due to the physician, some to the patient. Some men are entirely unfitted for genitourinary work. Some object to the time required for the practice of this method. But the time devoted to it is fully warranted. The failures due to the patient are far more numerous than those laid at the physician's door. There is the rebellious patient who will not heed his physician's orders, and the patient who cannot visit his physician at the necessary times. There are various defects, both congenital and acquired, as well as complications which cannot only interfere with effective irrigations, but may also prevent obtaining the results as promptly as is desirable. Among these are: A very tight preputial orifice; stenotic meatus; very large meatus; intraurethral abnormalities; epispadias and hypospadias; periurethral and paraurethral fistulas; balanitis and balanoposthitis; chancre and chancroid; cicatrices at the meatus; condylomas; fistulas; herpes progenitalis; infiltrations of the urethral crypts, glands, follicles and of the mucosa itself; paraphimosis; phimosis; prostatitis and spermatocystitis; stricture; and urinary abnormalities.

A Report on Tuberculin as a Means of Diagnosis.—J. D. Madison concludes that: (1) Patients may react to tuberculin and no evidence of tuberculosis be found at autopsy. (2) A number of cases reviewed seem to demonstrate that completely-healed tuberculosis may react. (3) Cases of proved tuberculosis may not react to the maximum doses. (4) The evidence is not conclusive that other diseases than tuberculosis may react to tuberculin. (5) The margin of error of the tuberculin test is considerable, and probably not less than 10 per cent. (6) The maximum dose should be higher than 4 mg., and not more than 10 mg. Small increasing doses are not advisable, as the reaction is not so likely to be distinct on account of the tolerance which may be produced. An initial dose of 3 to 5 mg. followed by the maximum dose is better. (7) The temperature should usually be normal before injections are given. When the temperature is distinctly above normal, a negative result is of no value, as these patients will frequently not respond at all, even to large doses. (8) It seems quite certain that the glycerin extract of tuberculin deteriorates, and a fresh bottle should frequently be opened, care being taken to keep it in a cool, dark place. The 5-per-cent. carbolic-acid solution should be made up on the day it is used, if possible. The writer believes that deterioration of tuberculin is the principal factor in producing delayed reactions. (9) It cannot be said that tuberculin injections are entirely without ill effects, but their use among suitable patients is no more dangerous than the use of chloroform and ether for diagnostic purposes, and is quite as justifiable as an early diagnosis of tuberculosis is of the greatest importance. (10) About 40 per cent. of all female patients admitted to the hospital (Danvers Insane Hospital) react to tuberculin.

Philadelphia Medical Journal, December 20, 1902.

Bronchitis and Bronchopneumonia from Inhalation of Irritants.—J. N. Hall states that in the past few years he has seen one or more instances of these conditions arise from six different kinds of irritants: Chlorine gas, sulphurous acid gas, formaldehyde, kerosene, smoke, and smoke containing some unknown acid fumes. He has sepaarted these cases from the ordinary inhalation pneumonias, and from suffocation by deadly gases. He gives the history of a case, illustrating each variety. Many cases of bronchitis originate from chemical irritants. They are generally far more painful in the beginning than those of the ordinary form. Bronchopneumonia may easily develop. Death may occur before the lungs are involved, presumably from œdema and spasm of the larynx. Death may ensue very quickly. Oxygen, theoretically, should be especially serviceable. The possibility of relief of laryngeal symptoms by intubation should be borne in mind. In many cases the mechanical impediment in the bronchi from swelling is an insuperable obstacle to recovery.

A Case of Adiposis Dolorosa, with Involvement of the Joints.—F. X. Dercum reports this case. The patient was a woman, aged sixty-one years. She had always suffered much from backache, but had no other illness previous to the onset of the present disease, which began about ten years ago. The first symptom was weakness of the legs, then of the back. After that, painful lumps of fat made their appearance at various points. The examination of the joints in this case, the author states, justifies the conclusion that there was present a marked thickening of the synovial membranes, and possibly of other structures in the neighborhood of the joints. There was a marked tendency to the formation of fringes and rice bodies. That this thickening is due, in part at least, to fatty infiltration, and that this fat is painful, just as is the fat in the lipomata on the surface of the body, affords the most reasonable explanation of the condition observed. It is probable also that an actual chronic synovitis is present. Rheumatism does not afford an adequate explanation of the conditions found, while rheumatoid arthritis is excluded by the absence of changes in the bones and cartilages.

The Lancet, December 13, 1902.

Ablation of the Crystalline Lens to Rectify High Myopia.—W. J. Collins reports nine cases, referring to previous papers on the subject. A perusal of the clinical histories shows that in all there was improvement of vision, which, in some instances, was very marked. This improvement without resort to glasses was a great practical benefit to the patients, as some were able to do work from which they had, on account of their infirmity, been previously excluded. In no case did any untoward symptoms follow the operation. Collins has never operated on both eyes, though several of the patients requested him so to do after appreciating the improvement of vision in the first eye from the operation. He thinks that the operation, in suitable cases, a limited class, is so reasonably safe, and attended often with such brilliant results, that it should be regarded as a recognized procedure in the treatment of high or advancing myopia in young persons.

Notes on Sleeping Sickness.—C. A. Wiggins details his experience with the disease, stating that the most striking sign of the disease is the expression. At the end of the first month the sufferer has simply a vacant expression, with a characteristic drooping of the lower lip downward and forward, so that all the lower teeth are seen; the lip is slightly swollen, and very dry and cracked. At the end of the second month the manner, like the expression, becomes listless and vacant, the face gets puffy, the upper eyelids begin to droop, and the lip hangs lower and is more cracked and dry. If the patient puts out his tongue, it is tremulous, and occasionally the hands, also, if they are held out. At the end of the third month everything is intensified. Saliva drips over the hanging lip unnoticed and unchecked, and the whole body is filthily dirty. There are marked tremors in all the limbs, especially in the arms, and the sufferer has to support himself with a long stick, to which he clings, as his limbs are very liable to give way suddenly, when he falls in a heap on the ground without attempting to put out his hands to save himself. The tremors are often choreic in character, and are always more exaggerated on the left side than on the right. At the end of the fourth month the sufferer cannot get about at all, but he lies on the ground in his hut without moving his position. He generally lies in one of three positions: (1) flat on the ground with the face downwards, the legs out straight, and the head resting on the hands and turned to one side; (2) doubled up on the left side, with all the limbs curled up; or (3) kneeling down and leaning forward with the forehead resting either on the ground or on the side of the hut. This last position looks most uncomfortable. During this last month the most horrible sores develop, and the patients are most unpleasant to see as they pass their motions as they lie, and a heap of saliva accumulates by the head and dried secretion and filth collect round the nostrils and eye. The eyes are closed, and the patients seem unable to open them; they are also unable to speak at this stage, which lasts from two to four weeks, when they die.

Infective Arthritis.—In the Bradshaw Lecture for the current year, Howard Marsh discusses arthritic inflammations seen in connection with pneumonia, typhoid fever, scarlatina, influenza, erysipelas, and rheumatism. He then considers the unclassified infections localizing themselves in the joints, and devotes a special heading to the acute arthritis of infants. Finally he gives the clinical histories of six clinical cases. Concerning the lesions found, Marsh notes that they vary considerably in different cases. In some they are slight and transient, and result from synovitis, attended with infiltration of the sub-synovial tissue, and with some, but only a limited amount, of serous effusion into the cavity of the joint. This is the case, *e.g.* in the arthritis which occurs in the early stage of scarlet fever and typhoid fever. In a second group, one, two, or more of the joints are painful, and swollen from effusion of fluid into the synovial cavity. These are the cases which have been so misleading in consequence of the close similarity of the appearances observed on clinical examination to those of acute rheumatism. Although at first merely turbid, the fluid in the joint, in some cases, soon becomes purulent. In the third group, the inflammatory process chiefly involves the periarticular tissues, and leads to considerable brawny or boggy swelling and to reddening of the skin, which is at the same time so stretched and shiny as to suggest the presence, or near approach, of suppuration. This is one of the most clearly-marked types of infective arthritis, and one with which we have long been familiar in some of the cases of gonococcal infection. In this form there is frequently no effusion into the cavity of the joint, and, though it seems imminent, suppuration very rarely occurs. Clinically, these cases run a very prolonged and tedious course; they may extend over several weeks, and some have lasted two or three months. Many are attended with pain, not only persistent but very severe, and they show a strong tendency to result in firm fibrous ankylosis, which, apparently, in some instances, gradually passes on by ossification of the new fibrous tissue to complete synostosis. In these respects they furnish a close parallel to one of the forms of arthritis which is met with in the course of the septicæmia which follows acute infective periostitis or osteomyelitis. A fourth group of cases includes those in which the arthritis is from the first acute and destructive. Suppuration takes place early and goes rapidly on to complete disorganization of the joint and often to the wide burrowing of pus, which has escaped from the synovial cavity along the intermuscular spaces of the limb. This fourth variety is met with in its most marked phase in pneumococcic arthritis. The various plans of treatment are then summarized. With a limited effusion, a splint and warm fomentation suffice; in the variety with fluid in the joint, the latter must be emptied and irrigated, the joint opened, if necessary, and adhesions broken down with the finger; in the plastic form, the prognosis is unfavorable, as there is a strong tendency to ankylosis. Warm boric or opium fomentations are required during the first stage; small blisters will promote absorption, and later massage to remove the brawny œdema of the soft parts.

Deutsche medicinische Wochenschrift, November 27, 1902.

Benign Adenoma of the Stomach Developing from a Gastric Ulcer.—Albu reports an interesting case. The tumor was first diagnosed five years subsequent to the initial appearance of the gastric ulcer. It was thought, on account of the clinical symptoms, to be carcinomatous in nature, and operative measures were undertaken. Upon opening the stomach the tumor was found to be about the size of a fist, and to have developed from the margin of the partially cicatrized gastric ulcer. Microscopical examination showed that it was typically adenomatous in structure. Since it must have been present for a long time, it is evident that it was benign in nature. Following the removal of the tumor, complete recovery ensued.

Early Diagnosis of Icterus.—Jac. Bouma agrees with Hamel concerning the importance in the early diagnosis of icterus of the detection of the bile pigments and salts in the serum previous to their appearance in the urine or the development of cutaneous discoloration. While Hamel relies upon the color of the clear serum as a guide to the excessive presence of bile salts in the same, Bouma thinks that a chemical examination is much more delicate and satisfactory. He also gives a modification of Hammarsten's method for the detection of these salts in the urine by means of which the urobilin is more easily differentiated from the bile pigments. To 8 c.c. of fresh acid urine 2 c.c. of a 10-per-cent. solution of calcium chloride is added. A weak ammonia solution is now slowly added, until the neutral point is reached, when a precipitation, which includes the bile salts, takes place, the urobilin remaining in solution. This precipitatum is dissolved in a mixture of 1 c.c. of Obermayer's reagent (29 $Fe_2 Cl_6$ in 1 liter of HCl) and 4 c.c. of absolute alcohol. If bile pigments are present, a greenish color is produced, which changes gradually to a bluish green. In testing serum one adds to 2 c.c. of the same 6 c.c. of distilled water, 1 c.c. of a normal solution of neutral sodium phosphate (NO_2 HPO_4) and 1 c.c. of a normal solution of barium chloride. This is then centrifuged, and the precipitum washed in water and again centrifuged, the final precipitum being dissolved in 1 c.c. of Obermayer's reagent and 4 c.c. of absolute alcohol. If there was the least trace of bile pigments present in the serum, the upper portion of this last solution will be of a bluish-green color. This test has frequently demonstrated the presence of bile pigments in the serum when the color of the latter was not in the least altered from the normal.

Berliner klinische Wochenschrift, December 1, 1902.

Antistreptococcus Serum.—Piorkowski believes that he has demonstrated the multiplicity of the various species of streptococci, in that he has prepared a powerful specific anti-serum from one of these species, which was isolated from the nasal secretion of a horse suffering from a contagious, purulent affection of the mucous membranes of the nose and throat peculiar to these animals. This serum, in doses of 10 c.c., is nearly always able to bring about the speedy cure of this disease, but is totally inefficient against diseases produced by other varieties of streptococci. Furthermore, in dilutions of 1-100 and above, it agglutinates the variety of streptococci by the means of which it has been produced, while upon other varieties of this organism it has no such action, or only produces their agglutination in dilutions of 1-25 and below.

Acute Circumscribed Œdema.—F. Mendel reports the instance of a family of twelve persons, running through four generations, nine of whom suffered from this disease. In six an acute circumscribed œdema of the glottis sooner or later developed, and produced instantaneous death. All suffered with intermittent attacks of the œdema for many years, but the glottis was never involved except in the fatal cases. Usually the œdema suddenly appeared in distinct and discrete spots upon various regions of the body, most frequently upon the backs of the hands and arms. In the particular member of this family who came under the observation of the author, the attacks were frequent—every two or three weeks—and the appearance of the eruption was very similar to an urticaria. It could be easily differentiated therefrom, however, by the fact that no itching was present. In the treatment diaphoretic measures were tried at first, without avail; later aspirin (3 gr. t.i.d.) was added, with good result, in that there soon occurred a disappearance of the œdema. Subsequent attacks were quickly cured by the aspirin alone. Indeed, so magical was the effect of this drug that it seems as though it should be regarded as a specific for this condition.

Münchener medicinische Wochenschrift, December 2, 1902.

Extent of Albumin Digestion in the Human Stomach with the Simultaneous Ingestion of Carbohydrates.—Ernst Heinrich finds, as the result of experimental observation, that during the first hour following the ingestion of finely-chopped cooked beef about one-third of the albumin contained therein is digested in the stomach. This takes place without the appearance of free HCl. If carbohydrates, such as rice, are ingested simultaneously with the meat, the proteolytic gastric action is increased about 10 per cent.

French and Italian Journals.

Osteomata.—Etienne Henrard reports three cases of osteomata caused by traumatism and diagnosed by radiography alone. In the first patient a fall on the shoulder caused three osteomata on the clavicle; in the second patient, radiography demonstrated an osteoma of the head of the humerus, and in the third, an osteoma of the olecranon. A fourth case, the most interesting perhaps, is that of a child, in which a fall on the elbow caused a hyperproduction of bone in the carpus.—*La Tribune Médicale*, November 26, 1902.

The Pathogenic Power of the Bacterium Coli on the Dog.—Giuseppe Loy-Peluffo, from his experimentation, concludes that there are very few varieties of the bacterium coli taken from the atmosphere which are capable of exercising pathogenic powers when inoculated into the circulating blood of a dog. Moreover, none of the pathogenic varieties of the bacterium isolated from the atmosphere and inoculated into the veins of dogs are capable of producing the lesions caused in the same animal by a pure culture of the icteroid bacillus isolated by Sanarelli.—*La Riforma Medica*, November 18, 1902.

Lumbar Hernia.—Jeannel declares that the etiology of lumbar hernia is absolutely unknown. It is probable that at least the majority of congenital lumbar hernias are provided with a peritoneal sac. The contents vary as in all hernias. As to the pathogeny, without daring to generalize, it appears, nevertheless, legitimate to distinguish two varieties of hernia: Hernia consecutive to a malformation; and hernia not apparently consecutive to a malformation. Immediately, or soon after birth, the small tumor is discovered. It is soft, and often increases in size when the child cries. It can not be cured spontaneously. The treatment varies with different writers. Some apply a bandage. Others perform a radical cure. The acquired lumbar hernia is one that develops a long time after birth, perhaps from a congenital malformation of the muscles of the region, at first insufficient to allow the passage of a hernia, but constituting a weak point, which strain or traumatism will weaken and cause to open for the hernia; or the muscles may be torn apart by injury; or a cold abscess of lumbar origin or an osteitis may open the way for a hernia; or muscular atrophy of vertebral origin, following paresis, may be the cause.—*Archives Provinciales de Chirurgie*, November 1, 1902.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 4, 1902.

ROBERT F. WEIR, M.D., PRESIDENT.

Medical Supervision of the Isthmian Canal.—The following resolutions were adopted:

Whereas, It is well known that the previous excavations for an isthmian canal have been attended by a large amount of illness and a heavy mortality, due mainly to malaria and yellow fever, and

Whereas, Recent medical discoveries have enabled the medical profession to control them to a marked degree,

Resolved, By the New York Academy of Medicine, that in their judgment the amplest powers should be given to the medical officer in charge of the sanitation of the canal, and to attain this end the medical officer should be a member of the Commission which the President of the United States is authorized to appoint to conduct the affairs of the canal; it is further

Resolved, That the Secretary of the Academy is authorized to forward this preamble and resolution to the President of the United States.

In Memoriam, Major Walter Reed.—On motion of Dr. E. G. JANEWAY the following resolution was also adopted:

Whereas, In the recent death of Major Walter Reed, U. S. A., the science of medicine has lost the one whose brilliant research led first to the demonstration of the transmission of yellow fever by the mosquito, and later to the practical removal of the disease from a large part of Cuba, and the prevention of its transmission to the shores of this country; be it

Resolved, That the New York Academy of Medicine records the greatness of the loss to science and mankind and its sympathy to the friends and'relatives of the deceased.

On the Need of a Radical Reform in the Teaching of Medicine to Senior Students.—Dr. WILLIAM OSLER, Professor of Medicine in the Johns Hopkins University, Baltimore, delivered an address on the subject. He opened his discourse by the statement that he had taken for his text the rather widely-circulated statement found in a recent report of the Surgeon-General, viz.: "Eighty-seven candidates, graduates of our medical schools, presented themselves before the medical board; eighteen were accepted." A further analysis showed that twenty-one were physically disqualified and that forty-eight withdrew or were rejected. This, the speaker thought, justified the rather sweeping title that he had chosen, for it should be remembered that this was the only competent and impartial board to sit in judgment upon the work of medical teachers. The special development of the medical school in the past twenty-five years had been in the direction of teaching practical science. Instead of a single laboratory devoted to anatomy, as in former years, numerous laboratories were now devoted to the many branches of medicine. The student of to-day no longer had a lecture-room knowledge, but a first-hand acquaintance with the things themselves. The work of the student in the first and second year had become exceedingly practical, and the question arose as to how the work of the third and fourth years could be made as practical. It was not in the systematic lecture, amphitheater, the clinic, or even the ward clinic, but in the whole relationship of the senior student to the hospital, that certain reforms were necessary. First, there should be a change in the conception of how medicine should be taught. The senior student should be started at once on his road of life. The graduate of a quarter of a century ago went out with only a little practical knowledge, and the latter increased in after year, only as his practice increased. In the ideal course the student started in fact as a practitioner; as an observer of disordered machines, with the structure and orderly functions of which he was already perfectly familiar. He should be taught how to observe and be given plenty of facts to observe, and the lessons would come out of the facts. It was a safe rule not to have any teaching except with a patient as a text. To educate the eye to see, the ear to hear and the finger to feel took time, and all that could be done was to start the student on the right path. The mistake was constantly made of trying to teach the student too much. He should be given good methods and a proper point of view, and all other needful things should be gradually added thereto.

Reform in the Hospital.—A second important reform needed was in the hospital itself. In the interest of the medical student, the profession and the public, the hospital authorities should be asked for much greater facilities than were at present enjoyed by the students of the majority of the medical schools. The work of the third and fourth years should be taken entirely out of the medical schools and be put into the hospitals. But an extraordinary difficulty would present itself. While there were institutions where students had all the privileges desired, there were others to which they were admitted by the side entrance, and quietly, to the amphitheater—by the back street if possible; and there were others which barred the student entirely. The work in a hospital in which there was no teaching was rarely first-class, and the hospital physician was apt to become slovenly unless he taught and was himself taught by his house physicians and students. The objection often raised that the patients did not like to have students in the wards was entirely fanciful, and in his experience it had been exactly the reverse, and he could claim to speak with some authority, as he had served as a hospital physician for twenty-five years, and had taught chiefly in the ward. With the exercise of ordinary discretion, and if one were actuated by kindly feelings toward his patients, there was not the slightest difficulty. In the present state of medicine it was difficult to carry on a modern hospital without the help of students, for the house staff has too much to do to attend to all of the routine work.

The Reform Needed.—How could these reforms be carried into effect? The speaker here narrated an experiment—the story of how he had been personally engaged in teaching medicine. The third-year student came to the out-patient department, and in it learned his medicine, and there only. He learned it in the amphitheater only on stated occasions. He or his associates met the class in the dispensary on three mornings in the week. An arrangement had been made by which a class of thirty or forty could be accommodated in a room built next to the out-patient department. This, of course, was a difficulty in an ordinary general dispensary, because of the lack of room and of proper accommodations. The patients were taken into this classroom in a less formal way than in the regular clinic. At the end of each month a "clinical round-up" was given, and at the end of the eight months the men who had held these "round-ups" made up a summary, which was then duplicated for the entire class. The students were encouraged to keep track of their cases, and report upon them, and if the patient went to the hospital the students were allowed to go into the wards to determine what progress the patient was making, and report upon the same. The students were systematically taught in groups physical diagnosis and history-taking up to Christmas, and then they were assigned in groups of three or four to the dispensary and worked up the cases under the supervision of the out-patient staff. This constituted the main portion of the clinical instruction in medicine obtained by these third-year students. Each student thus spent two or three hours, three times a week, in practical dispensary work, doing everything but prescribing for the patient. Three afternoons a week the student was instructed in practical microscopy in the laboratory, and one day in the week a general hospital clinic was given. There was no systematic lectures on theory. There was no talking on anything without a patient at hand as a text. The other three days in the week the students received practical instruction in surgery.

Line upon Line; Precept upon Precept.—The speaker said that he had a hospital service of from 105 to 125 beds. He had a group of men—seventeen at present—acting as clinical clerks in the hospital wards. Three mornings in the week he gave these students simple ward instruction, and on the alternate mornings his assistant did the same thing with these same students, carrying out what should be the motto of all medical teaching: "Precept must be upon precept, precept upon precept; line upon line, line upon line; here a little and there a little." On Saturday the groups from the medical, surgical, and obstetrical teaching met in the ampitheater, and then there was presented the experience of the week. For instance, the records of all the cases of pneumonia were presented upon the blackboard, and the morbid anatomy specimens for the week were shown. This was the "clearing-house" for the week.

Systematic Lectures.—Dr. Osler said he was not theoretically opposed to systematic lectures upon certain subjects. This was a point which every teacher should settle for himself. It would be a great mistake, he thought, ever to abolish all theoretical lectures in medicine. Occasionally a Trousseau appeared, who was worth hearing, but, ordinarily, systematic lectures on medicine were, in his opinion, no longer necessary. There were, of course, certain diseases which could not be demonstrated. The teacher, or one of his trusted assistants, gave a set lesson from time to time, and the students were systematically quizzed. This could be made an exceedingly attractive and valuable method of instruction, particularly if the teacher would take the trouble to announce the topics in advance. Thus, the students of the fourth year did work in the wards and in the ampitheater, and, in addition, Dr. Osler meets them one evening a week and discusses with them personally the clinical events of the week, more particularly the accidents and the mistakes, and the failures, their own and his. This quiet talk served to lessen the distance between the students and the teacher, which was, after all, a very important matter. This plan had been tried for five years, and from his own and the students' standpoint it appeared to work very satisfactorily. He would like to ask how many of the medical students in New York City, Philadelphia, Chicago, and other large medical centers had their rights, and were permitted to observe and study by hourly contact the numerous cases of such important diseases as pneumonia and typhoid fever. It was that which he called teaching medicine, and it was for that he was pleading.

Harvard's Reforms.—Prof. H. L. Burrell of Harvard University opened the discussion. He said that educational reform, during these past twenty years, had been gradually increasing in vigor, but the preparatory schools of this and other countries were at present really experimental stations. An important principle was, as had been said by President Eliot, to "train men for power;" another principle was to allow the student to acquire knowledge rather than to merely receive information. The whole country had watched with the keenest interest the development of education at the Johns Hopkins Medical School, where the distinguished faculty were singularly fortunate in having small classes, and, while listening and seeking for the truth, had yet recognized that the environment of each school, hospital, and city must, of necessity, be considered in adopting improved methods of instruction. There were three ways in which the teaching of medicine to senior students could be improved. The first was to have a curriculum which should consist of minimum required work and maximum elective opportunity. The minimum required work should consist of the absolutely essential knowledge of all fundamental studies necessary to make a well-informed physician, whether the student was to be a practitioner of medicine or was to devote himself to the science of medicine. The maximum elective should afford to students, after they had mastered the fundamental studies, the opportunity to acquire knowledge in any direction they might elect. In his opinion, the course of study in a medical school should cover a period of four years, three years to be devoted to the required, and one year to the elective, studies. The plan which had been adopted at the Harvard Medical School last June was as follows: (1) The fourth year to be elective without any restrictions; (2) the total number of hours required of each student to be one thousand; (3) certain courses to be recommended as fitting a student to become a general practitioner, or a specialist in, or teacher of, any department of medicine; (4) an advisory committee to be appointed with whom the students might consult concerning the selection of studies; (5) in general the forenoon hours to be devoted to practical work in hospitals and laboratories, and the afternoon hours to the lecture room and laboratories. The first year and a half was to be devoted to the study of anatomy, histology, physiology, physiological and pathological chemistry, pathology and bacteriology. The second year and a half, completing the three years, to be devoted to medicine, surgery, obstetrics, hygiene, pharmacology, dermatology, gynecology, pediatrics, neurology, syphilis, ophthalmology, otology, laryngology, legal medicine, and psychiatry. During these three years the student was to devote himself to these studies at their minimum. During the fourth year he might devote his one thousand hours of time to such electives as he might select.

The second method, which he hoped would be adopted by the Harvard Medical School, required all students, during the fourth year, to serve as clinical clerks and surgical dressers in the wards and out-patient departments of a hospital. The service should consist of four months as clinical clerk in the medical out-patient department, two months as clinical clerk in a medical ward, two months as a dresser in the surgical out-patient department, two months as surgical dresser in the surgical wards, and two-months' work as assistant in some elected special out-patient department. This plan would take six months of the student's whole time, and six months of his mornings or afternoons. It would necessitate the abolishment of the third-year vacation for a certain number of students, and although this might at first sight seem a hardship to the students, when it was considered that they were in a technical school acquiring the knowledge that was going to fit them to gain a livelihood, it was not too much to expect that some of the students should be willing to work during one summer of their four-years' course. This plan would be simple to carry into effect if the school had a hospital and could be made practical, even if the school did not have a hospital.

To make this plan effective it would be necessary that the three parties concerned, the student, the hospital, and the school, should each find it advantageous. It would be of advantage to the student, for he would gain that practical experience that he so keenly desired. It would be of advantage to the board of government of a hospital, for assistants would come to them from a responsible body, with regularity, having been trained for their duties. From the school's standpoint, the advantages were manifest. It would in an organized manner provide opportunity for students to acquire practical knowledge. The mornings or afternoons of the fourth year could be devoted to this practical work. The students should be under medical and surgical tutors, whose duty it should be to see that the agreement on the part of the school to furnish assistants to the hospital is fulfilled. An important function of the tutor would be to encourage the student to carry out a line of research work in clinical subjects, not so much for the value that would come from this research work to the science of medicine, as the habit acquired by the student to pursue an individual subject until completed. The remainder of the time in the fourth year should be devoted to laboratories and lectures. This plan was practical; the three parties concerned, student, hospital, and school, would all be benefited. The length of service of house officers, under this plan, might be readily shortened to a year, for the house officer would come to the hospital with greater experience.

The third way to improve teaching was to recognize clearly the scope and character of lectures and section work. The professors in a medical school should direct the work done in their departments, and the section work should be given to small classes. The more nearly personal the instruction was, the better. It should not be a clinical lecture, nor a clinical demonstration, but should be the drill of the individual student in the fundamental studies, *e. g.* drill in taking histories, in making physical diagnoses, in establishing the treatment of patients. The lecture, on the other hand, should be given to large classes; it should (1) present in a concentrated form the experience of mature teachers, and (2) it should present the advanced knowledge on selected special subjects. The lecture's great value, if properly given, was to serve as an inspiration to students to do better work.

In conclusion, the speaker said that reform in medical education was in the air; progress was to be made. The great metropolis of New York, with its wealth of clinical material, its skilled practitioners and its broad humanities, could readily become, by the concerted action of its schools and hospitals, the medical center of the world.

The Problem in Canada.—Professor ALEXANDER MCPHEDRAN of the University of Toronto was invited to take part in the discussion. He said that one feature of this subject had always been prominent in his mind, though it was often lost sight of on this continent, *i. e.* that the functions of the hospital are three-fold, viz.: (1) To care for the patients under its charge; (2) To train nurses for the care of the people outside who cannot go to a hospital, and (3) To train medical students to care for the poor in various parts of the country who cannot avail themselves of the advantages of the hospital. A hospital which failed to perform this three-fold function should not be looked upon as a thoroughly-equipped hospital. His insistence upon this point had borne fruit in Toronto, and had resulted in the opening of the hospitals to medical students. The plan followed by Dr. Osler was more easily carried out with small classes. When he had had about fifty or sixty students in the graduating class he had not found much difficulty in supplying them with the practical instruction, but now that the number was one hundred or more this difficulty had become far greater—indeed, he had come here for the purpose of finding out how he was to meet this difficulty. He found that there was a feeling in New York City that hospital patients objected to students in the wards, but he had found that very few patients, indeed, objected to students taking histories and examining the blood, and perhaps the contents of the stomach. It was largely a matter of custom, and patients acted largely according as they found they were expected to do, and he had noticed that where it was the custom for students to be in the hospital little objection was made, and that the patients even thought they were neglected if they did not receive as much attention from the students as some others. Again, in Toronto it was the custom to charge a small fee to the students, which was paid into the hospital fund, and under this system it seemed to him that the medical student had the right to receive practical instruction in the hospital. It was not a question of choice whether or not systematic lectures should be given in Toronto, for the law required that the students should receive certain lectures in order to secure a license to practise medicine. He was of the opinion that it would be better if fewer lectures were given, but he was not prepared to admit that they should be entirely abolished. He could not see how a student could get the practical instruction needed along with the theoretical knowledge in the course of four years. One case well and exhaustively studied was infinitely more valuable than the superficial study of a large number of clinical cases.

The Situation in New York.—Dr. E. G. JANEWAY said that the question of assimilating the method of instruction of the Johns Hopkins University with our own teaching here involved the consideration of the differences in the conditions under which the teaching was done. It should not be forgotten that the students in the Johns Hopkins University were specially selected. With regard to didactic lectures he was of the opinion that this was a question which should be left very largely to the judgment and discretion of the individual professor. It was not practicable in this city to turn such a large number of students into the hospital wards, and hence it became necessary to bring the patients and the students into the amphitheater. He believed that the instruction should be made, as far as possible, practical, but the conditions were such that, especially in some departments, they were compelled to give didactic lectures as an outline and guide to the systematization of the knowledge in the students' minds. This was really essential with students who were not specially selected, as in the Johns Hopkins University. He hoped he would soon see the hospitals of this city opened to students far more than they had been in the past. Even some of our public hospitals were not utilized for clinical instruction.

Opposed to Didactic Lectures and Electives.—Dr. W. B. JAMES said that even the needs of medical education should not be allowed to interfere with the primary and most important function of the hospital, the caring for the sick; nevertheless the hospitals should open their doors to the medical students and offer every facility for instruction, and the enormous mass of material for the study of disease should be utilized to the fullest. He confidently expected that in the near future there would be far fewer restrictions placed upon medical instruction in hospitals. He was quite sure there was enough unused clinical material in the dispensaries of New York City to equip fully for clinical instruction several first-rate medical schools. Every teacher must be a law unto himself in the matter of lectures. One well-known teacher had very pointedly observed, that the teacher who did not believe in the didactic lecture should most certainly avoid giving them. Much good practical instruction could be given to students in small sections. He believed the amphitheater clinic still occupied a most important position in medical education. It had very largely superseded, and he believed quite properly, the old instruction by didactic lectures. He had noticed that medical students, acting as substitutes on the house staffs of the hospitals, were very apt to waste a good deal of time, because their efforts were usually ill-directed by reason of their lack of medical knowledge. He was not at all a believer in electives in a four-year course. The tendency to specialism came all too soon, and it would probably result in turning out a more one-sided set of men than at present. The whole four years should be devoted to giving a symmetrical view of the entire field of medicine, with all its specialties.

Limitations of Bedside Instruction and Restrictions Imposed by State Examining Boards.—Dr. W. GILMAN THOMPSON thought that Dr. Osler had shown an inconsistency because he had inveighed against the didactic lecture as a means of instructing a large number, and yet he had at the same time shown his own ability to instruct a large audience by this same despised didactic lecture. With regard to the large proportion of candidates rejected at the army and navy examinations, he would say that these examinations include history and languages in addition to medicine, and, moreover, the conditions of the service were such as not always to attract the best men. These examinations could hardly be said to be more representative than the examinations of many State licensing boards. One should be careful to avoid giving the medical student a mere catalogue of medical topics. The laboratory instruction could be very much overdone, and it might prove as useless to the student who intended to enter the general practice of medicine as to teach him the bookbinders' art because some of his books might in time need binding. He would begin the practical instruction of medical students to a slight extent in the second year. It was quite a task at the present time for the student simply to learn the nomenclature. For example, in Professor Welch's recent Huxley lecture Dr. Thompson said he had counted twenty-five words about which he knew almost nothing. The aim should be to turn out well-balanced practitioners of medicine, so far as this could be done in a reasonable time. A great deal depended upon whether or not the students had received previous college training; also upon the size of the class, the relation of the school to the hospital and the things which the State Examiners insisted upon the student's knowing if he would obtain a license to practise medicine. Surely anyone who had looked over the questions asked at many of the State Board examinations must see that practical instruction is not enough. He was not one of those who favored the extensive use of the didactic lecture; still, such lectures were useful for the inculcation of certain general principles. There was danger of giving too much bedside instruction and making such teaching more like a picture book. It was impossible to demonstrate, for example, all the symptoms and signs of a disease in a particular case. There were many limitations to such instruction. Again, it was impossible in any ordinary hospital service to command the clinical material so fully as to give the instruction according to a system or preconceived order. The instruction needed for passing examinations by the State boards and competitive examinations for positions on hospital house staffs demanded systematic didactic instruction.

Practical Instruction in Obstetrics.—Dr. E. B. Cragin said that the department of obstetrics of the College of Physicians and Surgeons of this city had been struggling for five years with the problem of how best to give bedside instruction in this branch. The conditions would, at first sight, appear to be peculiarly favorable at this college, because the Sloane Maternity Hospital might be looked upon as the laboratory of the Chair of Obstetrics. Again, it should be remembered that the problem was how to bring 200 students before the patient in the hospital each year. About the only way was to divide the class into small sections of six. Each section of the fourth-year class lives in the hospital for two weeks, and while this method was far from ideal, it seemed to him far better than a year of theoretical lectures. He was heartily in accord with those who favored the recitation plan, for, a good groundwork in theory should be given in the first part of the year, and later on this should be supplemented by clinical instruction.

Dr. Ellsworth Eliot said that the didactic lecture in surgery had an important function in teaching. Surgery was changing so constantly that the students became confused unless guided by the authority of the instructor or lecturer. Recitations were useful by fixing the theoretical part of the subject in the mind. He would like to know how much the students in surgery were allowed to examine patients in the wards of the Johns Hopkins Hospital.

Dr. Osler closed the discussion. His knowledge of the army examining boards, he said, had impressed him so deeply that he felt that the title of his paper had been justified. The State examining boards could not be looked upon as a standard; some of them were the most senilely antique things in this country, and gave only theoretical examinations. What he pleaded for, and pleaded for earnestly, was that the medical student should have better facilities in his third and fourth year for utilizing the colossal material which now goes to waste in our dispensaries and hospital wards. He pleaded for the closer affiliation between the patient and the medical student. The ordinary ward class was not much better than the ordinary amphitheater lecture or didactic lecture. What was wanted was an intimate contact of the student and teacher. Such a system of instruction would almost do away with medicine from a theoretical standpoint. It was not the teacher, the textbook, or the lecture that was going to teach the student, but the patient, and he must see patients and patients and patients. The hungry sheep look up and are not fed upon the proper food, and they will not be until there is a closer affiliation between the out-patient department and the hospital wards with the students. Any young man could make a good reputation in an out-patient department, provided he had students to spur him on to do his best work.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 18, 1902.

Robert F. Weir, M.D., President.

Symposium on Gallstone Surgery.—This subject was considered in the following papers:

Some Practical Points in the Anatomy of the Gall-bladder Region.—Dr. George E. Brewer presented this, the opening paper He said that the important points in the anatomy of this region were: (1) A knowledge of the chief nerve trunks of the abdominal wall; (2) the normal position, size and shape of the gall-bladder and ducts, and of certain constant lymph nodes; (3) certain variations from the normal in these structures; (4) variations in the blood supply of the liver and gall-bladder; (5) the relation of the duodenal orifice at the common bile duct. The incision, when in the median line, should be so planned as to avoid dividing the intercostal nerves. Any incision which exposed the gall-bladder and ducts sufficiently must necessarily divide one or more of these nerve trunks. If, however, an incision through the rectus muscle were employed, extending from a point 1 cm. below the eighth costal cartilage to 1 cm. above the umbilicus, only the ninth intercostal nerve would be divided. In the lower portion of the gall-bladder was a large semilunal fold attached to two-thirds of the circumference of the wall. There was also another, though smaller, valvular fold, and between the two was what had been called "the pelvis of the gall-bladder." This "basin" was sometimes the seat of a stone, and the latter might very easily be overlooked during operation, being hidden by one of these folds. From one hundred measurements of the gall-bladder that he had made, the average was found to be 10 cm. The mucous membrane of the cystic duct contained a series of folds or valves, varying in number from four to twenty. These valves generally prevented the passage of a probe in either direction. The average length of the common duct was found to be 7.5 cm., and its diameter 20 mm., while the diameter of the common hepatic duct was 16 mm. According to Quain, the gall-bladder was occasionally absent. Occasionally a fully developed gall-bladder was found embedded in liver tissue. Cases of double gall-bladder had been reported, and also cases of left-sided gall-bladder without transposition of the viscera Membranous partitions had been found in the gall-bladder, generally longitudinal in direction. The gall-bladder was also occasionally shaped like a horseshoe. Most of these abnormalities were so rare as to be looked upon only as anatomical curiosities. In the one hundred subjects studied by Dr. Brewer there were no very important anatomical variations, though there were considerable variations in the length of the mesentery of the gall-bladder, thus affecting the mobility of this organ The cystic duct, owing to the presence of numerous folds of mucous membrane, rarely permitted the passage of a probe. A degree of patency of the cystic duct sufficient to allow of the passage of a probe should be looked upon as a pathological condition. The author said that he had made fifty dissections with a view to studying the arterial supply, and had found that in only three did this supply correspond with the description usually given in the text-books. The rights or free extremity of the gastrohepatic omentum frequently contains branches of the artery derived from other sources than the hepatic artery, and this should be remembered in tearing away the gastrohepatic omentum.

The Causes of Gallstones.—Dr. A. J. Lartigau read this paper.i He said that it had been shown that the phenomena of cholelithiasis were closely related with bacterial nvasion of the gall-bladder. The first direct experimental demonstration was in 1897, and consisted in the production of a number of stones experimentally by the direct inoculation of guinea-pigs with various bacteria. It was found also that the introduction of sterile foreign bodies, even when associated with bile stagnation, did not result in gallstone formation. His own studies showed that the growth of microorganisms, such as the colon and typhoid bacilli, was but slightly inhibited by bile. Other experiments were successful in causing the artificial production of gallstones, the shortest period being six weeks. The microorganisms originally used were always recovered. The effect of mixed infection was also studied in a few instances, and with negative result. It had been claimed that bacteria, especially at the height of digestion, pass through the normal intestinal mucosa into the portal circulation, thus reaching the liver where they might be destroyed or eliminated into the body at large, or into the bile. This seemed to be the case under normal conditions, and was still more marked when inflammatory changes were present. It was probable that the portal route from the intestine was a common channel of infection of the gall-bladder in cases of cholelithiasis. Certain experiments also showed that in cases of systemic infection the gall-bladder might become infected and cholelithiasis result. The speaker laid great stress upon the stagnation of the bile as an important factor in the production of cholelithiasis.

The Diagnosis of Gallstones.—Dr. J. B. Murphy of Chicago discussed this subject. He said that statistics showed that from 6.94 to 12.2 per cent. of all autopsies showed the presence of gallstones, and yet in only a small proportion of these cases had the symptoms of cholelithiasis been noted during life. The previous speaker had shown that there were several channels of infection, and that the bile was frequently infected. He believed the chief cause of the disturbance of gallstones after their formation was a secondary infection. The effect of that secondary infection depended (1) upon its virulence; (2) upon the products of the infection, and (3) upon the retention of these products under pressure in the various portions of the biliary tract. For instance, the secondary infection caused an increased secretion, and this secretion carried with it the stones into the pelvis of the gall-bladder. If the infection were mild and the calculus large, the stone would be forced into the neck or close to the neck in the pelvis of the gall-bladder. With this, the patient would experience a sense of distress, usually terminating in vomiting. This manifestation was even more common than an attack characterized by pain, nausea, vomiting, jaundice, and the disappearance of the symptoms. It was just in this class that the greatest number of errors arose. In these cases there was no elevation of temperature—simply pain, nausea, and vomiting. Many of these patients would say that if they could only vomit, they would be relieved of their "gastralgia." He believed that the calculus became impacted at the neck of the gall-bladder, and, the mucus passing into the duct, the attack ceased. In a second class of cases there was a moderately virulent type of infection. Here the onset was characterized by pain, nausea, and vomiting, marked sensitiveness on deep pressure in the right hypochondriac region, inability to take a deep inspiration when the fingers were dug under the margin of the ribs. The temperature rarely rose above 101° F., and was usually between 99.5° and 100.5° F. The patients so affected were usually elderly persons. The attack terminated by the forcing of the calculus into the gall-bladder or into the cystic duct. The tenderness would be relieved in a week or ten days. In the virulent infections of the gall-bladder there was often a rapid and complete necrosis of the gall-bladder. The attack was characterized by pain, chill, nausea, and vomiting, and an elevation of the temperature to 102.5° or even 104° F It rarely exceeded this last point. The fundus of the gall-bladder was poorly supplied with lymphatics as compared with the neck, and hence infection of the fundus caused less elevation of temperature than infection of the neck of the gall-bladder. When the stone passed into the duct and there was no colic, it was either because the stone was too large or too small. Gallstone colic was not due to the obstruction of the duct, but to the passage of a foreign body through a canal. If the stone were sufficiently large to overcome muscular contraction of the canal completely, then there was an absence of muscular spasm or colic. Sometimes the stone was retained in the pelvis of the gall-bladder for a long time. The temperature in these cases was not of the remittent type seen so frequently in general sepsis, but was of a distinctly intermittent and irregular type. The temperature would rise quickly to 103° or 105° F. The temperature would remain at this height for a few hours or days, and would then drop as suddenly to normal, and, after an interval, the same sudden rise, sustained temperature, and sudden fall would be repeated. This peculiar range of temperature was exceedingly characteristic of cholangeitis. When the stone was located in the common duct, there would be chill and fever, and the intermission was just as classic as in the cases already referred to. When the gall-bladder was infected, it became contracted; when obstructed without infection, the gall-bladder became enlarged. This was a point in the differential diagnosis between gallstone obstruction and malignant disease which had been pointed out by Courvoisier, and it was entirely in consonance with his own clinical experience. It was frequently stated that there was a complete intermission of the jaundice in cases in which the gallstone was in the common duct, but this had not been his experience, for, although the marked jaundice of the skin disappeared, he had always found a persistence of the jaundice of the sclerotic. It might be laid down as a general rule that a jaundice not preceded by a colic was not of gallstone origin, and that a jaundice preceded by a colic was of gallstone origin.

The Present Status of Surgery of the Gall-bladder and Bile Tracts.—Dr. W. S. Mayo of Rochester, Minn., presented this paper. He said that we had grown so accustomed to look upon the colic as the chief symptom of gallstones that the more chronic symptoms were commonly overlooked. Both infection and lack of drainage were factors in the production of cholelithiasis. The resulting disturbance depended upon the acuteness of the infection and the distensibility of the gall-bladder. In this respect the gall-bladder possessed a marked advantage over the appendix. Normally, bile had been shown to be free from microorganisms, and to be a poor culture medium, but thick or stagnant bile was a much better culture medium. All cases of slumbering gallstones probably contain bacteria, and need only some interference with drainage or a reinfection from the intestine to bring them into activity. In view of the probability of further extension of the trouble, it seemed wise to remove gallstones early. In over 2,000 operations of this kind, in the hands of six surgeons, there was not a single instance of re-formation of the stones. Repeated infections with bad drainage cause the walls of the bladder to become infiltrated with inflammatory products, and causes greater tension and more urgent symptoms. The changes found in the bladder reminded one of those found in appendicitis. In 454 operative cases he had found cancer of the gall-bladder or bile passages in about 5 per cent., and a distinct history of previous colic was elicited in these cases. He had never operated upon a patient who had passed a stone in the fæces without finding one or more other stones in the gall-bladder. The infection of the liver ducts introduced an element of uncertainty in the prognosis. Out of the 454 cases there were twenty-three examples of chronic cholecystitis without the formation of stones, and these were cured by opening and draining the gall-bladder. He had recently heard from nineteen of these patients, fifteen reporting themselves as well, two as improved, and two as unimproved. Cholecystostomy and drainage was the operation of choice. Drainage should be continued until the bile became normal. The operation was very safe, as the gall-bladder was fastened to the abdominal incision, and the position was such as to secure good drainage. Kehr said that the hepatic duct required drainage in 37 per cent. of the cases. In cases of stones in the common duct drainage of the hepatic duct was a necessity.

Dr. W. W. Keen of Philadelphia opened the discussion. He said he had been especially interested in the paper of Dr. Lartigau with reference to the causes of gallstones, for the reason that five years ago, when writing his little book on the surgical complications of typhoid fever, on coming to the subject of gall-bladder infection he found there had been a few instances in which gallstones had been examined bacteriologically and typhoid bacilli discovered in them, and presumably the nucleus and cause of the gallstones. Up to that time he believed there had been no experimental proof whatever save one isolated case. Since then much admirable work had been done in connection with the experimental production of gallstones, so that there could be no possible doubt regarding their etiological relation to the typhoid bacilli. This was especially interesting when it was remembered that in the bone marrow, the spleen, and the gall-bladder the typhoid bacilli were the most persistent. The very commonly-known fact, that gallstones are so much more frequent in women than in men, showed that there must be some other relation than that simply of infection. Perhaps this was explained by what had been said about the necessity for a free circulation of the bile. He believed that the costume of women and the constriction around the waist constituted an important factor in the production of gallstones in addition to bacteriological infection. He thought Dr. Mayo was right in his selection of cholecystostomy and drainage as *the* operation of choice. It gave much better results than cholecystectomy and cholecystenterostomy. On the other hand, there were occasional cases in which the operation of choice was not cholecystostomy. Gallstones sometimes played very curious tricks. He remembered a very stout woman upon whom he had done another operation some years ago. At that time it had not occurred to him to investigate the condition of the gall-bladder. Immediately after the operation she began to have severe diffused pain in the abdomen. He was greatly worried, fearing the beginning of an infection of the peritoneum, but suddenly, on the third day, a torrent of gallstones was discharged from the rectum. There were collected as trophies of that attack 101 gallstones. The question of performing a gallstone operation depended largely upon the condition of the blood. In no case of any considerable, and especially of deep or long-continued, jaundice should one neglect to study the coagulation time of the blood. If the coagulation time were not sufficiently short, it was well to put the patient upon chloride of calcium, in doses of five grains, three times a day, until the coagulation time had been reduced to, say, five minutes.

Dr. Munro of Boston reported the following fatal case: The patient was a woman of twenty years, who gave a history of having suffered from abdominal pain. Three days before operation she had an attack of acute abdominal pain, localized in the region of the appendix. The latter was found at operation to be normal, but almost at this level was an inflamed gall bladder. No gallstones were found. The pulse was rapid during the operation, and for some reason, not clear at the time, she seemed too weak for a cholecystectomy. She did not respond well to stimulants and died fifteen hours after operation. A careful autopsy was made. The bacteriological examination was practically negative. The anatomical diagnosis was suppurative cholecystitis, beginning peritonitis, and status lymphaticus. The thymus was 10 cm. long and was soft and succulent.

Officers Elected.—Dr. Andrew H Smith, *President;* Dr. M Allen Starr, *Vice-President;* Dr. Herman L. Collyer, *Treasurer; Member of Committee on Admission*, Dr. J. Milton Mabbott; *Member of Committee on Library*, Dr. Joseph Collins.

SECTION ON ORTHOPEDIC SURGERY.

Meeting of December 19, 1902.

Reception Given to Prof. Adolf Lorenz of Vienna

Dr. Robt. F. Weir, President of the Academy, opened the meeting, and then placed it in the hands of Dr. George R. Elliott, Chairman of the Orthopedic Section.

Dr. Weir remarked that an introduction of Professor Lorenz was almost superfluous, as he was well known, not only in his own department, but in advanced science generally; that his demonstrations of his methods in this country were of educational value to the American physician, as well as of great benefit to the special department of orthopedic surgery. The opportunity of actually seeing Dr. Lorenz at work offered a chance of learning altogether different from and in advance of simply reading about his methods, as object teaching is a superior educational method. His special peculiarities were observed in a way not revealed from his writings.

Dr. Elliott said, as Chairman of the Section of Orthopedic Surgery, it was a great pleasure to give expression to the honor the section felt in having Professor Lorenz present. It was also a great personal satisfaction to know that his work had received some of the recognition it deserved.

From medical men much had been said about the great force he used. It was true that Professor Lorenz was a very strong man, but those who had seen him operate must have observed that the essential element in his operations was the intelligent direction of that force, graduating it to overcome the existing resistance of the contracted tissues, so that they were reduced to a state of flaccidity. Dr. Elliott further said that six years ago when he reported his first case of congenital dislocation of the hip, successfully treated by this method (Medical Record, May 29, 1897), he made the following statement. "The operation we have just considered is a real advance in surgery, and, throwing all enthusiasm aside, I feel convinced that it will soon be performed with strikingly good results in all civilized parts of the world." It was unnecessary to say how that predication had been fulfilled. Dr. Elliott expressed pleasure in calling upon Professor Lorenz to address the meeting.

Dr. Lorenz's Address.—(See p. 1001.)

Dr. V. P. Gibney said that he would like to tell the Fellows of the Academy of Medicine just how much he had learned from Professor Lorenz. All the information given us about bearing weight on the joints, about correcting deformities, about destruction of muscles which produce deformity, especially adductors, was something of a revelation.

At first Dr. Lorenz's views about the management of hip-disease, club-foot, and wry-neck seemed antiquated, but when he began to elaborate them he felt that he was in the presence of a master. Lorenz tells us that the pain in hip-disease comes in exacerbations, and does not agree with me regarding the use of traction. He says we employ traction for too long a period, causing atrophy of muscle and destroying functional activity; that it should be used only for short periods; he does not allow deformity to occur at all. When Lorenz was asked if he aimed to get functional restoration, he replied "yes, five or ten times in 100."

Dr. Gibney thought all orthopedic surgeons should aim to get perfect restoration of function. There was great reason for reflection, and whether or not we were all wrong about traction remained to be seen. Those of you present at one of the clinics this week saw his ability to take a virgin club-foot, an extreme case, and within half an hour he and his able assistant, Dr. Mueller, had "pulpified the foot, so to speak, had rendered it like a "wet rag." Lorenz regarded age as no deterrent in the bloodless correction of club-foot. When the bones could not be managed by manual force he used instruments.

Dr. Royal Whitman said that he felt pleased to find that Dr. Lorenz considered good reposition with increased functional ability a satisfactory result; this gave him great encouragement in some of his own cases in which he had been inclined to consider the results as disappointing.

He further remarked that he had gained valuable information from Dr. Lorenz in the treatment of the disability following fracture of the femur. Lorenz attempted to get the limb into an anterior position and hold it abducted and extended, enabling the patient to walk. This was done under an anæsthetic; he considered it an important advance in the treatment of such disabled cases.

Dr. R. H. Sayre said he had learned much from Dr. Lorenz's visit. After having seen him operate, he realized exactly what he did in a way he had not acquired from reading about his work and methods. In his early practice, as he looked back, he now saw where he had not used sufficient force nor sufficiently long retention of the parts in position.

Dr. Shaffer said he thought Dr. Lorenz had done a great deal for orthopedic surgery. Remembering the days of the elder Sayre, Taylor, and Knight, and that America might be called the birthplace of orthopedic surgery, yet there had come to us from abroad a great teacher and one who had taught us. He remarked that many had seen him operate and do what was considered almost impossible. He had, at his clinic, presented to Dr. Lorenz a stubborn, resistant case of congenital club-foot, expecting to see the doctor refuse to operate; nothing of the kind occurred, Dr. Lorenz corrected the deformity, as a matter of course. He said that the Lorenz clinic in Vienna had become the Mecca for orthopedists, and that yearly Americans were flocking there.

Dr. Weir, President of the Academy of Medicine, proposed a resolution that a vote of thanks be offered Dr. Lorenz, which was unanimously adopted.

The meeting then adjourned and was followed by a reception to Professor Lorenz.

SECTION ON SURGERY.

Stated Meeting, Held December 8, 1902.

Robert T. Morris, M.D., Chairman pro tem.

Cases of Fracture of the Scapula.—Dr. B. Tilton presented a man who, four months ago, had fallen about twelve feet, striking on the shoulder. He sustained a fracture of the clavicle, which was treated, but the physician in attendance did not notice a fracture of the scapula, and it remained undetected until the man came to the New York Hospital. Examination then showed a pseudoarthrosis of the body of the scapula. The man had been treated for four weeks by a spica bandage on the shoulder, and while there was no pain, false motion still existed. Dr. Tilton also presented another case of fracture of the scapula, occurring in a man who had fallen from a scaffold. This fracture involved the spine of the scapula, a rather unusual situation. There was now no pain, crepitus, or false motion, but the cállus was perfectly evident.

Cases of Ununited Fracture.—Dr. Tilton showed an ununited fracture of the arm, four weeks after the injury. The fragments had been rubbed together from time to time, but without stimulating the formation of callus, and an open operation was now advised. The next patient was a man, who had broken his tibia on February 4, 1902. It had been treated in the usual way by plaster casts, but union had not taken place. Last summer Dr. Tilton drilled into the callus in various directions, and, although this resulted in some improvement, it was not satisfactory. For the last two months the man had been allowed to walk around with a short splint, so that he walked on the fragments. Since then, and particularly during the past month, the improvement had been very noticeable. During this time he had been on thyroid extract, but whether or not this had had anything to do with the improvement could not be said. The speaker had found this treatment very satisfactory.

Fracture of the Ulna.—Dr. Tilton also presented a little girl, who had fallen three weeks ago, sustaining a fracture of the ulna. She had been treated by light anterior and posterior plaster splints.

Dislocation and Fracture of the Shoulder.—Dr. J. A. Hartwell said that a man had come into the Lincoln Hospital last June with a dislocation of the shoulder. He had cut down upon it, and by cutting the subscapularis muscle had succeeded in reducing the dislocation. In the latter part of August the function of the joint was perfectly restored, but shortly afterward, in a fit of melancholy, the man committed suicide.

Musculospiral Paralysis.—Dr. Hartwell also presented a man who had been injured in some machinery. When seen by the speaker the next day there was complete musculospiral paralysis. There was also a fracture of the clavicle, with severe contusions, and consequently operation was postponed until the following day. At that time an incision was made on the outer side of the arm, and the triceps muscle exposed. This muscle was found to be torn a good deal, and both fragments of the bone were protruding. The musculospiral nerve was finally found, and was not ruptured, so that the paralysis was apparently the result of stretching of this nerve. The bones were united by two sutures of forty-day chromic catgut, and the arm put up in extension for fourteen days. At the end of that time there was still wrist-drop. It was then put up in the flexed position for four weeks or more. At the end of two months he began to obtain slight use of the extensors of the hand. During the past month he had obtained complete use of the muscles. About six or seven weeks after the injury the reaction of degeneration was present, but was very slight.

Fracture of Tubercle of Tibia.—Dr. M. W. Ware presented a boy of fourteen years, who had fractured the tubercle of the tibia. He had first seen him about six hours after the injury, which had been produced by the boy's dropping suddenly from a ring swing and striking the floor with the feet as the body fell backward. The patella was found to be at a much higher level on the right than on the left side. The foot was kept in extension, and by means of zinc oxide plaster strips the tubercle was kept in connection with the shaft. A plaster-of-Paris bandage was applied from the foot to the middle of the thigh. The speaker said that strictly this should be called a separation of the epiphysis, because it was really such at the age of this lad. Of the ten reported cases all had occurred in gymnasts. Examination with the *x*-ray and the fluoroscope in the case presented showed a distinct epiphysis.

Neglected Fracture of the Patella.—Dr. Fréderic Griffith presented a woman, thirty-two years of age, who had fallen a short distance, striking upon the knee and fracturing it. This was about one year ago, but she refused proper treatment, and the injury repaired itself by fibrous union.

Persistent Dislocation of the Shoulder; Operation.—Dr Carl Beck presented a young man who had dislocated his right shoulder about one year ago, and it was reduced by a companion. The second dislocation took place some months later, and was reduced at the hospital. A third dislocation having taken place recently, the patient reduced it himself. Exploratory incision by Dr, Beck showed nothing but an unusual relaxation of the capsule. The capsule was accordingly narrowed by a purse-string suture, and a hole was drilled into the bones with the object of securing adhesions.

Appendicitis and Intestinal Obstruction.—Dr. C H. Peck reported this case. On October 4 the operation for appendicitis was done, and on November 9 intestinal obstruction developed. At the operation for the relief of this condition it was found that a double band of small intestine extended from the ileocæcal junction to the left upper lateral portion of the abdomen, and bound down the ileum. The obstruction was relieved, and the patient made a good recovery.

A Cured Carcinoma of the Breast.—Dr. Peck also presented a woman upon whom he had operated on September 12, 1889, for an extensive carcinoma of the breast. The axillary glands and breast were extirpated in the old way, but there had been no recurrence, though the case had passed the three-year limit.

An Operation for Epispadias.—Dr. Edward M. Foote presented a young boy upon whom he had done several operations for the relief of an epispadias. At the beginning there was about one-half of the pendulous portion of the urethra wanting. A point of interest in the case was the novel procedure adopted of freeing the foreskin and turning it down like the top of a buggy. It was utilized in completing the urethra.

Large Hernia after Kraske Operation.—Dr. Foote also presented a woman, forty-four years of age. Eight years ago she began to have great trouble with defecation, and subsequently was treated at the Presbyterian Hospital by dilatation of the rectum. Six years ago about six inches of the lower portion of the rectum were resected. Following this, two or three plastic operations were done. About six months after the resection a hernia appeared, and it was now of such great size as to give the woman much discomfort. It was not reducible. There was no history of syphilis, and he suspected the original trouble was tubercular.

Retroperitoneal Pelvic Abscess from Retrocæcal Appendicitis.—Dr. A. Ernest Gallant presented a paper reporting three cases of a heretofore undescribed form of appendicular abscess, first noticed when operating on a girl of fourteen years, with a retrocæcal, gangrenous appendicitis. Through a McBurney incision the index finger was being wormed between the caput coli and the pelvic wall when it entered a cavity which extended into the pelvis. Over a pint of foul-smelling pus was evacuated. The cul-de-sac of Douglas was free from any signs of peritonitis, and the uterus and appendages were normal. A finger introduced into the vagina came in contact with the finger from above, and demonstrated that the abscess had made its way behind the pelvic peritoneum, and was located between the posterior vaginal wall and the rectum. A large drainage tube was inserted through a vaginal puncture, and the region of the cæcum packed with sterile gauze. Recovery was uneventful. Two other cases were also reported. One was that of a girl of ten years, seen a few months later, who presented the same condition. On account of the smallness of the vagina no drain was used. This patient also recovered. The third case was that of a man of forty years, who for four years had been under antiluetic treatment to control early symptoms of locomotor ataxia. He was found to be suffering from a post-cæcal appendicitis, with a bulging of the post-pelvic peritoneal wall. On introducing the finger, eight or ten ounces of a clear, faintly yellowish fluid escaped, in which floated numerous white flocculi, such as are met with in tuberculous or gummatous collections. The patient failed to retain sufficient nourishment, gradually became exhausted, and died on the tenth day. At this time the wound manifested no signs of a reparative nature. Dr. Gallant said that these cases were characterized by a rather subacute onset; the patients were not ill enough to consult a physician until the eighth or tenth day, when in each of his cases there was found a tumefaction extending from the false pelvis toward the umbilicus. This was tympanitic on percussion, and proved to be the caput coli displaced upward against the rigid abdominal wall. In the first case the seat of most intense pain was in the left false pelvis. Rectal examination in the third case showed a mass bulging in front of the rectum, but not in the rectovesical pouch.

The Practical Value of a Detailed Diagnosis in Fracture.—Dr. Carl Beck read this paper, and illustrated it by cases and skiagraphs. He said that reduction meant immediate relief of pressure and improper reduction meant injury to the tissues. If the fracture were deeply seated, the experienced surgeon would sometimes guess rightly with regard to the nature of the fracture, but it was not until union had occurred that he knew whether he had guessed correctly or not. There was no occasion at the present day for such haphazard work, because of the valuable aid afforded by the Rontgen ray. In fractures of the forearm and leg, where there were two bones, the displacement might take place in different directions, as had been shown by the Rontgen ray. He was becoming very skeptical about the diagnosis of excessive callus formation, because the Rontgen ray had shown him that in many cases in which he had formerly made this diagnosis there was no such callus formation, but that he had mistaken for this an unreduced fragment. Nélaton had been ridiculed for asserting that, in fractures of the lower end of the radius, the styloid process of the ulna was often torn off, but the Röntgen ray in modern times had shown that this eminent surgeon was right, and that this occurred in from 30 to 40 per cent. of the cases. A man was presented with fracture of the arm. A large splinter of bone was not discovered until examined with the Rontgen ray, and thus it was easy to persuade the patient of the necessity of an operation. This was done and the splinter removed. If it had not been discovered early there would have been interference with the biceps and triceps muscles. For fractures of the metacarpal bones he had made use of a rubber tube to hold the fragments in better position, and he had also applied this same principle at times to certain fractures of the radius and ulna.

Dr C. A Elsberg said he was interested in Dr Griffith's case, and would suggest that the effort be made to freshen the edges of the fragments and suture them together. Within two weeks passive motion and massage should be begun, the fragments being kept in proper position. He thought there would be a very good chance of obtaining a good functional result, even in such an old case.

Dr John Rogers remarked that he did not remember to have seen an old fracture of the patella that was so reducible.

Dr. M. W Ware said that, as a rule, these fractures resulted from muscular contraction, and hence it was interesting to note that in this case the woman fell upon the patella. This also explained the occurrence of comminution. An open operation should be done, and the fragments brought together. He would like to ask if, in the case of ununited fracture, a trial had been given to Bier's treatment by constriction with the rubber bandage. The plaster splints employed by Dr Tilton he had found very useful.

Dr. C. Beck said he was much interested in the operation on the case of epispadias. In 1897 he had published a description of an original operation for this condition. In that operation he utilized the extensibility of the urethra, dislocating it forward. It was remarkable to what extent the urethra could be thus displaced. The advantages of this method were obvious, although in some cases of penile epispadias it failed. The urethra should be dissected free, and then pulled forward, and a roof made by tunneling the glans.

Dr. Joseph Wiener, Jr., said that last summer he had operated upon a boy of twelve years for epispadias by the method just described by Dr. Beck. The boy had had a conconstant dribbling from the epispadias for several weeks previously, and there was a fluctuating tumor that caused much doubt as to the correct diagnosis. On making a suprapubic incision the tumor was found to be a diverticulum of the bladder. The latter was opened and drained. Everything went well for a few days after the operation, and then the lad developed scarlet fever. The sutures had to be removed, and there was slight retraction of the urethra. He had seen the boy recently and his condition was practically normal. The boy was able now to hold the urine all night, and for three or four hours by day.

Dr. A. V. Moschcowitz, referring to the case of hernia after a Kraske operation, said that some years ago he had removed the coccyx from a man for intractable coccygodynia, and yet, following this operation, there developed a hernia about the size of the fist.

Dr. Joseph Wiener said that this interesting case seemed to him an excellent argument in favor of abandoning the Kraske operation. He did not think to-day one was justified in doing this operation according to the method laid down by its originator. There was no occasion, moreover, in a woman to excise any part of the scrotum; all that was necessary was to turn back a flap from the sacrum.

Dr. A. Ernest Gallant thought Dr. Beck was right in maintaining that fractures into the wrist-joint were not true Colles' fractures. They had been originally described by an Irish surgeon named Barton about the year 1863. Biers claimed that callus was formed much more rapidly under passive congestion. On the other hand, the opponents of the ambulatory treatment and massage had claimed that this resulted in an excess of callus formation. He was personally in favor of the early use of massage in fractures, even before the reduction of the same. Reference was made to a case in which he had made use of a spiral strip of adhesive plaster to prevent the inward rotation of the lower end of the radius.

Dr. Robert T. Morris remarked that by the firm application of a rubber bandage for a few minutes in a case of recent fracture it was sometimes possible to reduce the œdema to such an extent that one could examine the fracture with ease and satisfaction. He thought this would accomplish the same thing as the massage, only more easily and quickly.

Dr. Beck objected to this use of the rubber bandage, on the ground that the pressure of such a bandage upon the injured tissues was apt to prove injurious. Moreover, cases of paralysis had been repeatedly reported. He was quite aware that of what had been described as Barton's fracture, but the one he had alluded to in his paper was not this fracture, but an intraarticular fracture, a piece of the radius having been entirely separated and shifted upward. A great many fractures would heal in spite of treatment, as was well demonstrated by the records of the treatment fractures by quacks. Fractures having but little displacement would give good results from massage, yet he would very strongly advise against massage treatment as a regular therapeutic procedure, for he had seen very great deformity follow its use. He had had a very large experience in the treatment of fractures, and should have obtained the necessary expertness of touch, yet he was free to confess that in nearly half of his cases of fracture the Rontgen ray had shown him that his diagnosis by palpation was erroneous.

Book Reviews.

The Mattison Method in Morphinism. By J. B. Mattison, M.D., Medical Director, Brooklyn Home for Narcotic Inebriates. New York: E. B. Treat & Co., 1902.

This work is very small (40 pages). The author advocates continued full doses of bromides, and gradual decrease of the opiates. After sedation has been secured, codeine is given. Directions for meeting emergencies and complications are given.

Die Zunge und ihre Begleit-Erscheinungen bei Krankheiten. Von Dr. Carl Rosenthal. Berlin: August Hirschwald, 1902.

The author here presents, in well-arranged chapters, the various appearances and conditions of tongue attending different diseases, as well as the diseases proper of the organ itself. The work is based on scattered literature, and a rather wide experience in hospital and private practice. The work of 250 pages has not a single illustration. The reasons given for this is that, aside from pathological conditions of the tongue itself, the appearances are not readily reproduced, and for reproductions of the latter there are several atlases to which one can refer. The work is well written, and will aid in the diagnosis of a great variety of disorders.

Manual of Bacteriology. By Richard T. Hewlett, M.D., M.R.C.P.; D.P.H. (London). Second edition. Philadelphia: P. Blakiston's Son & Co., 1902.

The new, revised edition will be cordially welcomed by the busy practitioner who needs a ready guide for his laboratory work. The first portion of the book is devoted to general considerations of bacteria; their life history, their toxins, and antitoxins; and to the methods employed for their growth and clinical examination. In an excellent, terse fashion the author gives the essential characteristics of every bacterium, its toxin, antitoxin, and sera, and its agglutination reaction, and appended to each such description is a short sketch of the methods for its clinical examination. Short chapters on the bacteriology of the air, water, and soil on antiseptics and disinfectants, with an appendix on bacterial remedies (antitoxins and sera), are found at the end of the book. For those who need only the essentials of bacteriology, the volume will be especially valuable.

A Treatise on Diseases of the Anus, Rectum, and Pelvic Colon. By James P. Tuttle, A.M., M.D. Eight colored plates; 338 illustrations. New York: D. Appleton & Co., 1902.

The book forms a valuable contribution to the literature of these diseases. The author has embodied in this work the knowledge he has gained from a wide and extended practice in these affections, together with a most thorough study of the literature bearing upon this subject. In one respect only may he be criticized, to wit: he has made his book too large; terseness and conciseness are as important in descriptions as clearness, and add materially to the force of statements. The illustrations are good; the book-making fine; the subject matter is well classified. There is an excellent chapter on diagnosis and examination. Altogether the book is an excellent one, and should be read with interest and profit by all.

A Nurse's Guide for the Operating Room. By Nicholas Senn, M.D., Ph.D., L.L.D., Professor of Surgery, Rush Medical College, etc., etc. Chicago: W. T. Keener & Co., 1902.

This guide of 128 pages is published under the direction of the Sisters of Charity, St. Joseph's Hospital of Chicago. The feature of the work is the directions for preparing the operating room, instruments, etc. Made up largely of abstracts of lectures delivered by the author; evidences of wound complications are detailed so that the nurse may be on the lookout for early signs. Illustrations of many instruments are given.

The Treatment of Tabetic Ataxia by Means of Systematic Exercise. By Dr. H. S. Frenkel, Medical Superintendent of the Sanatorium "Freihof" in Heiden (Switzerland). Only authorized English edition, translated and edited by L. Freyberger, M.D., Vienna, M.R.C.P., London, M.R.C.S., England. With 132 illustrations. Philadelphia: P. Blakiston's Son & Co., 1902.

The subject is classified in two parts: (1) "General Part," in which is described the various types of tabetic ataxia; the causation of incoordination; the methods of examination for tabetic ataxia and disturbances of sensibility; and the influence of "hypotonia" (lack of muscular balance) on the attitude of the body, etc. (2) "Special Part," illustrating the different forms of exercises and apparatus utilized in this special method of treatment.

The writer gives a very clear and concise description of the pathology and mechanism of incoordination, which is deserving of careful perusal. He emphasizes the necessity of great care and watchfulness in carrying out this plan of systematic exercise, particularly in advanced cases. Its contraindications, however, are not sufficiently dwelt upon, neither is adequate expression given as to its inadaptability, in a large proportion of cases, on account of the absence of suitable facilities, nor is it clearly stated that the method is purely educational. As all tabetic patients are not ataxic, and as all ataxic tabetics are not suitable subjects for such exercises, this method will be found to have well-defined limitations. The author states that "the present edition is not a translation of Frenkel's book, but an adaptation of it to the requirements of the medical practitioner." It contains all the salient features of Frenkel's original treatise, but, being the first and only work of its kind in the English language, it will undoubtedly prove a welcome addition to the library of many American readers.

An Introduction to Dermatology. By Norman Walker, M.D., Fellow of the Royal College of Physicians of Edinburgh, etc. Second edition, revised and enlarged. New York: Wm. Wood & Company, 1902.

Dr. Walker has a true sense of the requirements of the student at large, and of the attributes of the successful teacher. This insight he has brought to bear upon his pen-point, and the resulting work proved so far successful that he has had again to become a scribe and record what has transpired of importance in dermatology since June, 1899. This task he has accomplished without greatly enlarging the original, or changing its character. The simplicity of make-up and avoidance of all unnecessary details was the feature of the book which made teachers recommend it to those of their students whom they knew had neither the time nor inclination to go to the root of dermatology, or to enter into the discussions of theories, or read the *pros* or *cons* of most questions. In scarcely any other work of recent years has one come nearer teaching dermatology as it should be taught to the average student than in that of which the author has just presented a new edition, with 43 full-page plates and 47 illustrations in the text.

It is by no means a faultless book, and some of the illustrations are open to criticism, but it gives so much by comparison with what it leaves out, that it deserves special mention.

Outlines of Physiology. By Edward Groves Jones, M.D. Philadelphia: P. Blakiston's Son & Co., 1902.

Within 416 pages the author has endeavored to compress the important facts of human physiology, together with enough notice of anatomical structures and relations to make these facts intelligible to the reader. On the whole, this task has been well done. The descriptions are clear, and the facts are well presented. We believe, however, that the book is too concise for use, except as a very elementary book, in the medical curriculum. It seems to us that physiology is too important a subject to be presented to the medical student in such elementary form. The medical practitioner should know fully as much of the present state of physiological science as he does of anatomy. In fact, the former subject should be ever present in his mind and his knowledge of it as exhaustive as possible. If the student does not have this impressed upon his mind in the medical college, he will experience greater difficulty in acquiring that knowledge in after life. We should regret, therefore, to see this work adopted as the only textbook on this subject placed in his hands. As an introduction to more detailed study, we believe the work can be highly commended.

Über die Behandlung der Kinderkrankheiten. Von Dr. H. Neumann. Berlin: Oscar Coblentz, 1902.

The third edition of this book, or compilation of letters, is intended to convey answers to questions which arise daily in the treatment of children. Many interesting features are described. The management of the newly born is written from a modern standpoint. The author insists on the application of a sterile cheese cloth bandage or roller around the umbilicus. He warns against septic infection through the umbilicus, and advises against "bathing until the cord drops off." The danger of infection from fæces and microorganisms in this region are considered—so the wisdom of the author's advice will be appreciated. "Wrapping the cord in cotton is wrong," says the author, unscientific, and one of the means of producing umbilical sepsis. He also maintains a distinct relationship between scrofulosis and tuberculosis, and points to a series of misleading symptoms—and then to positive symptoms identifying this disease. Very many serviceable formulæ are given. The careful attention to detail, the advice given from personal experience, the manner of prescribing, dosage of drugs, will be valuable to the busy practitioner, and especially so to the beginner in medicine.

The Diseases of Infancy and Childhood. By L. Emmett Holt, M.D., LL.D. Second Edition, revised and enlarged. New York: D. Appleton & Co., 1902.

The revision of this book has been carried out without any change in the general arrangement. The author has rewritten several chapters and many changes are noticeable. The value of pathology in the elucidation of symptoms and diagnosis is recognized. Many illustrations of post mortems, photographs of pathological conditions, will aid those seeking information regarding this important branch of pediatrics. Considerable space is given to all details regarding infant feeding. The diseases of the newly-born child are carefully described. Illustrations showing the technique of "stomach washing," also the proper method of "syringing the nose," always serve to impress the reader. The chapter on diphtheria is one that can be improved. More especially that portion relating to "nutrition in diphtheria." In speaking of extubation, page 499, the author mentions the value of a full dose of morphine prior to removing the tube. Antispasmodics, such as sodium bromide, might be mentioned. The dorsal method of intubation is also worth noting. The method is especially valuable when we are hampered in emergencies by lack of proper assistants. The first edition was so well received that we can safely predict a cordial reception for the second edition.

Mother and Child. By Edward P. Davis, A.M., M.D. Philadelphia: J. B. Lippincott Company, 1902.

The development of an infant depends upon its careful management. Attention to all details—of clothing, of bathing, of feeding, of room temperature, etc.—are so important that every book bearing on this subject must be welcome. The writer states that the book comprises experience gained in his own practice, hence all young physicians will welcome this book as a guide by one trained in this special branch of medicine. The prevention of disease can be commenced in the nursery, by giving nature and its requirements due consideration.

Books Received.

The Proceedings of the Charaka Club. 8vo. Vol. I. 97 pages, illustrated. William Wood & Company, New York. Price, $3.50 net.

A Textbook of Clinical Medicine. By Clarence Bartlett, M.D. 8vo. 976 pages. Illustrated. Boericke & Tafel, Philadelphia, Pa. Price, cloth, $7.00 net; half morocco, $8.00 net.

Recollections of the Old Quarter. By Wm. S. Gordon, M.D. 12mo. 142 pages. Illustrated. Moose Bros. & Company, Lynchburg, Va.

The Physician's Visiting List for 1903. P. Blakiston's Son & Co., Philadelphia. Price, $1.00 net.

Obstetrical Nursing for Nurses and Students. By Henry Enos Tuley, M.D. 12mo. 198 pages. Illustrated. G. P. Engelhard & Co., Chicago, Ill. Price, cloth, $1.00 net.

Flowers of Song from Many Lands. By Frederick Rowland Marvin. Royal octavo. 138 pages. Pafraets Book Co., Troy, N. Y.

A Textbook of Nursing. By Clara Weeks-Shaw. 8vo. 397 pages. Illustrated. Third edition. D. Appleton & Co., New York.

Cancer and Other Tumors of the Breast. By Charles Creighton, M.D. 8vo. 296 pages. Illustrated. Williams & Norgate, London, England. Price, 20 shillings net.

Manual of Antenatal Pathology and Hygiene. By J. W. Ballantyne, M.D. 527 pages. 8vo. Illustrated. William Wood & Co., New York. Price, $5.00 net.

Lessons and Laboratory Exercises in Bacteriology. By Allen J. Smith, M.D. 8vo. 298 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia. Price, $1.50 net.

The Earth in Relation to the Preservation and Destruction of Contagia. 12mo. 257 pages. By George Vivian Poore, M.D. Longmans, Green & Co., New York.

Malarial Fever—Its Cause, Prevention, and Treatment. By Ronald Ross, F.R.C.S. Ninth edition. 8vo. 68 pages. Longmans, Green & Co., New York.

The Nursing Profession: How and Where to Train. By Sir Henry Burdett, K.C.B. 12mo. 373 pages. The Scientific Press, Ltd., London. Price, 2 shillings.

Thirty-third Annual Report of the State Board of Health of Massachusetts. 8vo. 615 pages. Wright & Potter Printing Co., Boston, Mass.

Die Erkrankungen der Nieren. By Prof. Dr. H. Senator. Royal octavo. 525 pages. Alfred Holder, Berlin, Germany.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 20, 1902:

	Cases.	Deaths.
Measles	145	7
Diphtheria and croup	383	44
Scarlet fever	178	11
Smallpox	1	..
Varicella	105	..
Tuberculosis	202	139
Typhoid fever	99	18
Cerebrospinal meningitis	..	..

Some Parasites Found in Syphilis.—Max Schüller has been studying the tissues of syphilitics in various stages of the disease and has found present certain structures which have much in common with those he has already described as being the causative agents of carcinoma. The organisms found in the luetic tissues he considers may, like those of carcinoma, be held to be members of some group of hitherto unknown protozoa. The author describes in great detail the various staining methods, etc., necessary to demonstrate the organisms, and gives numerous illustrations of them *in situ* in the tissues. They consist mainly of two forms which may easily be obtained in fresh smears from primary lesions. The first form, which the author names "large capsules," when well preserved usually appear as somewhat pyriform or three-cornered bodies of brownish yellow color. Their contents are of a darker shade, while the shell is of a glistening yellowish tinge. Under a high power small knob-like elevations are distinctly to be seen. Nucleated masses are also to be seen which apparently are the extruded protoplasmic contents of the capsules. The second form consists of much smaller rounded bodies somewhat lighter in color, having a double contour, and which exhibit distinct radial striations. These are termed by the author "young organisms," as in his culture experiments they appeared to develop partly in the interior of the larger capsules and partly by fission. The author's investigations embraced studies of smears and sections from chancres, enlarged glands, condylomata, gummata, joint tissues, etc., taken from patients in the three stages of the disease and from those suffering from hereditary lues. In all of these, structures similar to those described, and also many modified forms, were discovered. Some culture and inoculation experiments on animals are also detailed, though these are still incomplete and do not offer conclusive evidence.—*Centralblatt fur Bakteriologie, etc*

Actinomycosis Hominis in America, with Report of Six Cases.—William G. Erving gives an interesting review of six cases, which are now reported for the first time. He presents several conclusions: The cases are scattered widely throughout the country, though most of them are reported from the large medical centers. Of ninety-six cases reported in this country, less than 20 per cent. came from Southern States. As to the sex, seventy-two were males, twenty-three females, while in five the sex was not mentioned. The youngest patient was a child of six years, the oldest a man of seventy years. There was a wide range of occupation. In twenty-four cases, or 36 per cent., the patients had had much to do with live stock and grain. In one instance the disease continued but four weeks, in another, thirteen years. Usually there is no definite history of infection. As the disease occurs in man, it is probably in a large majority of cases contracted from animals, especially cattle, in which actinomycosis is not uncommon; or, in common with cattle, from grain. The clinical characteristics vary greatly with the region of the body involved. Diagnosis should never be positive without the finding of the organism—the ray fungus. As to location, the primary lesion occurred in the cervico-facial region in fifty-three cases. Although the course of the disease is sluggish, extension is prone to follow. The prognosis depends largely upon the location of the disease, the pulmonary cases showing the highest mortality, the cervico-facial the lowest. From results, it seems advisable to excise completely the affected tissues wherever possible. —*Bulletin of the Johns Hopkins Hospital.*

A Case of Non-Surgical Premature Menopause.—Josephine Walter describes a case, and says that her aim has been to point out that (1) Premature menopause can occur without any previous or subsequent disease; (2) It is not necessarily preceded by any change in generative organs; (3) Any changes found in these organs are probably postmenopastic or due to disease, not at all related to the menopause; (4) Premature, as well as normal, menopause is due chiefly to atrophy, inhibition, or disease of a local menstrual ganglion and nerve plexus, rather than disease or atrophy of generative organs.—*The American Journal of Obstetrics.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending December 20, 1902:

INDEX.

A

Abdomen, fibroma of the wall of the, 390; foreign bodies left in the cavity of the, how to prevent the occurrence, 615; gunshot wound of the, with intestinal perforations, 449; peculiar tumor of the, 347; suture of operative wounds of the, 596; treatment of contusions of the, 227; treatment of wounds of the, in war, 200, 627.
Abdominal pain in typhoid fever, 936; pressure, local and pulmonary effects of, 669; surgery, drainage in, 552.
Abortion, peritonitis following attempted, 107.
Aboulia, 801; of chronic alcoholism, 438.
Accident insurance policies, septicæmia clause in, 190.
Acetonæmia following an operation for appendicitis, 30, 911.
Achondroplasia, cases of, 656, 876.
Achylia gastrica, relation of pernicious anæmia to, 828.
Acidity, gastric, 343.
Acromegaly, a case of, 25; with diabetes, 157.
Acroparæsthesia, 669; following traumatism, 711.
Actinic rays in minor surgery, 782.
Actinomycosis, 106; anorectal, 471.
Acute, significance of term, 861.
Addison's disease, suprarenal extract in, 440.
Adenitis, epidemic of non-suppurative cervical, 115; surgical treatment of tuberculous cervical, 269.
Adenoids, fatal hemorrhage following the removal of, 515; post-operative treatment of, 972.
Adiposis dolorosa with involvement of the joints, 1028.
Adrenalin, 147; in epithelioma of the eyelid, 294.
Advertising, a new phase of professional, 944.
Ague, environment as a cause of, 467.
Air in the veins, treatment of, 551; passages, foreign body in the, for seventy-two days, 908; pillows, sanitary inflation of, 469; tract, importance of early treatment of catarrhal conditions of the upper, in children, 730.
Alaska, quarantine station in, 101.
Albany, milk supply of, 820.
Albumin, Bence Jones, 126; effect of carbohydrates on the digestion of, 1029; origin of, in the urine, 467.
Albuminuria following severe exercise, 635.
Albumosuria, myelopathic, 627; of the pernicious anæmia type, 225.
Alcohol, air contaminated with, 660; declaration against, 1025; dietetic and medicinal value of, 217; disease due to the abuse of, 783; influence of, an infection, 143; mental dissolution the result of, 750; question of, 600, 671, 900; relation of insanity to, 819, use of, in therapeutics and as a beverage, 103, 1000.
Alcoholism, 438, 940; aboulia of chronic, 438.
Aldrich, N. B., out-of-door treatment, 336.
Alkalies, use of, in relieving pain, 751.
Allen, Charles Warrenne, the present status of radiotherapy in cutaneous diseases and cancer, 762.
Allyn, H. S., the mosquito theory of yellow-fever infection in Brazil, 585.
Alpha Omega Alpha Society, 543.
Ambylopia, toxic, 755.
Amboceptors, complementophile group of, 106; production, hæmolytic, by serum inoculation, 389.
Ambulance call, a wireless, 262; carriage of patients in, 854; surgeons, 259; surgeons, license for, 502; surgeons, rules in regard to, 582.
American Association of Life Insurance Examiners, 18.
American Association of Obstetricians and Gynecologists, 552.
American Electro-Therapeutic Association, 472.
American Laryngological Association, 112.
American Neurological Association, 152.
American Orthopedic Association, 231.
American Pediatric Society, 72.
American Proctological Society, 62.
American Public Health Association, 991.
American School of Medicine at Beyroot, Syria, 747, 1026.
American Surgical Association, 28.
Ametropia, wrinkles from, 596.
Ammonium compounds, comparative toxicity of, 709.
Amputation, retractor for, 357.
Amœbæ, parasitic, 748.
Amyl nitrite, burn of the eye by, 626.
Amyx, Robert F., a gunshot wound of the abdomen, inflicting nineteen perforations of the intestines and four lacerations of the mesentery, with many, 449.
Anæmia, ballooning for, 400; pulse, 590; in ankylostomiasis, 144; lead, blood changes in, 549; pathology of pernicious, 865; pernicious, changes in the spinal cord in, 427; pernicious, hypertrophy of the liver in, 268; relation of pernicious, to achylia gastrica, 828; repeated small hemorrhages as a cause of, 545; secondary, of the pernicious type with jaundice, 266; spinal-cord condition in severe, 185; splenic, 514.
Anæsthesia, complications of, 987; methods of surgical, 25; nitrous oxide, air, and chloroform, 829; new method of spinal, 1000.
Anæsthetic, a Javanese, 559; ethyl bromide as a primary, 192.
Anæsthetics, choice between, 387, 507.
Anastomosis, intestinal, 104.
Aneurysm, aortic, 227, 303, 346; calcification of the walls of a cardiac, 24; double cardiac, 507; gelatin in, 107, 187; inequality of the pupils in thoracic, 145; of the ductus arteriosus, 238; of the extremities, radical cure of, 34; a seldom described symptom of, 345; symptoms of, without adequate explanation, 865; varicose, of the saphena magna mistaken for a femoral hernia, 590.
Angina diphtheroides Vincenti, 106; pectoris, 343; pectoris, 964, 996; pectoris, treatment of, 27; typhoid, 23.
Angiomata, hot water injections in, 678, 945.
Angiotripsy as a substitute for ligation of arteries, 307.
Anguish, 787.
Ani prolapsus, treatment of, in children, 358.
Animal diseases and animal food, report on, 991.
Ankylosis, muscular interposition in the treatment of osseous, 268.
Ankylostoma duodenale, life history of the, 591.
Ankylostomiasis, 144; peculiar marking of the tongue in, 68, 591.
Antitoxin, damages for death from impure, 8[illegible]; production and control of, 788; value of diphtheria, 710.
Anxious states in mental maladies, 432.
Aorta, insufficiency of the, 26; rhythmical head shaking in disease of the, 69.
Aortic valve, traumatic disease of the, 918.
Aphasia due to head injury, 225; motor, with hemianæsthesia but no hemiplegia, 909; puerperal, 225; relief of, by trephining, 188; uræmic, 624.
Apoplexy in a youth, 862.
Appendages, operations upon the uterine, for sterility, 881, 912.
Appendicitis, 555, 907, 909; a case of, 955; acetonæmia following an operation for, 30, 911; American views on the treatment of, 219; and pyosalpinx, 798; Broca's views on the treatment of, 853; chronic, and right movable kidney, 869; Dieulafoy's views on, 343; dulness in, 345, 613; French statistics on, 944; fulminating, 946; importance of toxic phenomena in, 306; in the early part of the last century, 83; in women, pelvic suppuration complicating, 946; indications for operation in, 630; irrational starvation treatment of, 554; malaria as a complicating factor in the diagnosis of, 54; medical treatment of, 627; operative treatment of, 177, 620; parotitis following, 861; pregnancy complicated by, 427; recurrent, 906; some phases of, 66, 533; tuberculous, 269; typhoidal, in children, 73; ultimate results of operations for, 624.
Appendix, a misplaced, 594; cancer of the, 224, 289; foreign bodies in the 513; removal of the, 63; removal of the, when the abdomen is opened for other reasons, 708; the normal, 906; use for the, in the treatment of colitis, 201.
Arctic winter, effect of the, upon the nervous system, 619.
Argyrol in acute gonorrhœa, 574; in diseases of the nose, throat, and ear, 810.
Arm, passive carrying function of the, 236; support for the, 503.
Army, dearth of surgeons in the U. S., 720; foreign service medical corps in the, 902; medical school, 826; organization for the medical department of the, in active service, 195; proposed journal of the medical department of the British, 264; report of the Surgeon-General of the, 817; surgeon in Cromwell's time, 379, uniform of the medical department of the, 99.
Arsenic in food, 139; therapeutic value of, 750.
Arterial tension, 817.
Arteriosclerosis in early life, 635; spinal, 158.
Artery, rare lesion of, 390; resection of, 389.
Arteritis, syphilitic, 590.
Arthritis, bacteriology of, 279; deformans, 476, 709; deformans in a child, 593; diet in, 510; infective, 1028; monarticular, 811; rheumatoid, 456.
Arytenoid cartilage, changes in the form of, seen in singers and actors, 115.
Ascites, Morrison's operation in, 306 with abdominal tumors, 267.

Asphyxia complicating anæsthesia, 987; from carbonic oxide, 831; neonatorum, artificial respiration in, 266; neonatorum, infusion through the umbilical vein in, 160.
Association of Military Surgeons of the United States, 195.
Asthenopia, malarial causation of, 572.
Asthma, bronchial, and allied disorders, 546.
Asylums, tuberculosis in, 938.
Atrophy, pseudomuscular, 156.
Atropine, intestinal action of, 785.
Auscultatory percussion, a modified method of, 782.
Australia, quacks in, 138.
Autointoxication, 65; a study in, 709; cyclic vomiting in, 147; in relation to mental and nervous diseases, 709; of a new-born child, 390; reflex action in relation to, 937; simulating pneumonia, 636; with unusual urinary findings. 77.
Automobiles, discrimination against physicians in licensing, 915; the deadly, 220; use of, 854.
Axilla, hypertrophy of the skin glands in the, in puerperæ, 266.

B

Bacillus, aerogenes capsulatus in the blood, 949; diphtheriæ, varieties of, 238; tuberculosis, relation of the acid-fast bacteria to, 239.
Back brace, 236.
Bacteria, acid-fast, relation of, to the tubercle bacillus, 239; ; digestion of, 391; exaltation of the virulence of, by passage outside the animal body, 757; influence of intestinal, upon nutrition, 159; low temperature not fatal to, 575; method of fixing without drying, 124; virulence of, 106.
Bacteriology, progress in, 191.
Bacteriolytic serum-complements in disease, 911.
Baker, J. N., the primary treatment of railway injuries, 407.
Baldwin, J. F., a very rare fracture of the lower end of the femur, 595
Ballooning for anæmia, 400.
Bandler, Samuel Wyllis, the most frequent form of vaginal hernia, its etiology and treatment, 644.
Banti's disease, new form of treatment of, 815; three cases of, 388.
Barber shop, syphilis in the, 936, 986.
Bartlett, Frank H., a good physician, 479.
Baruch, Simon, observations on German therapeutics, 972.
Bashore, Harvey B., sanitary protection for rural districts, 413.
Bates, Wm. H., disappearance of, 663.
Baths, gifts of public, for New York, 99; public, 339.
Baum, F., the so-called Cargile membrane, 183.
Beatson's operation, ultimate result of, 72, 587, 627, 710.
Beck, Carl, the medico-legal value of the Röntgen rays, 202.
Beer, consumption of, in Germany, 360.
Belgian, Society of Surgery, 261.
Belladonna in children's diseases, 230.
Bellenger, P. L., post-typhoidal paralysis, 594.
Bellevue Hospital, reorganization of, 458.
Bence Jones, albumin, nature of, 26.
Berg, Henry W., pulmonary sypbilis simulating pulmonary tuberculosis, 926, 952.
Beriberi at Diego Garcia, 471; diet in relation to, 981; discussion on, 310; etiology of, 771.
Berlin, post-graduate study in, 63.
Bermuda, typhoid fever in, 1026.
Beyrout, American School of Medicine at, 747, 1026
Bichloride, intravenous injection of, 335.
Bile, influence of, on the resisting power of erythrocytes, 629.
Bile-ducts, diseases of the, 512.
Bilharzia hæmatobia, eosinophilia associated with, 988; in Cyprus, 313.
Biliary acids, influence of, on surface tension, 465.
Biogenesis and heredity, 763.
Birth rate, civilization in relation to, 39.
Blackwater fever, 225.
Bladder, extirpation of the, for cancer, 517; neuralgia of the, 342; permanent drainage in tuberculosis of the, 29; removal of the, for cancer, 29; suprapubic cystotomy for tumors of the, 943; ulcer of the, 143.
Blistering by chloral hydrate, 478.
Blodgett, John H., three phases of pancreatic disease, with report of cases, 930.
Blood, differentiation of, by means of serum, 66; in burns of the skin, 748; in its relation to surgical diagnosis, 656; origin of basophilic granules in the red cells, 863; quantitative changes in the, in pulmonary tuberculosis, 133; serum diagnosis of, 628.
Bloodletting in gynecology, 640.
Blood, pressure in disease, 514; in mental disease, 105.
Blount, Anna E., a case of premature delivery with unusual temperature course, 356.
Blushing, pathological forms of emotional, 471.
Boer war, casualties in the, 98; military medical conditions in the 197,
Bolo wounds, 381.
Bone-grafting, new methods of, 104.

Erdmann, John F., intussusception with a report of three additional operative cases, 5.
Errors, popular, 359.
Eructations, explosive, 669.
Eruption, itching, in children, 187.
Erysipelas, associated with scarlet fever, 469; ferri perchloride in large doses in, 376.
Erythema, hemorrhagic exudative, 269; simplex marginatum, 430.
Erythrocytes, influence of bile on the resisting power of, 629.
Estivoautumnal fever, bilious remittent, 136; chlorosis complicated by, 395; Manhattan Island and its environs, 369.
Etiology, recent discoveries in the domain of, 667.
Ether, administration of, 387.
Ethics, medical, 700.
Eustachian tube, electrolysis in the 558.
Exercise, albuminuria following, 635; effect of, upon the heart and circulation, 505.
Exophthalmic goiter, 920; phenomenon of, 468; electricity in, 752; hygienic treatment of, 550; operative treatment of, 34, 510, 697; pathogenesis and surgical treatment of, 492; with peculiar features, 862;.
Exostosis, multiple hereditary, 628.
Eye, artificial, cul-de-sac for securing, 342; burn of, by amyl nitrite, 626; enucleation of the, 342; extraction of iron from the vitreous by means of the giant magnet, 661; functional derangements of the, 784; general symptoms associated with diseases of the, 64; penetrating injuries of the, 129; progress in diseases of the, 191; rôle of toxins in inflammation of the, 948; significance of the prominent, 561; sterilizing instruments for use on the, 68; sympathetic diseases of the, 755; treatment of injuries of the, 587.
Eyelids, carcinoma of the, 65; epithelioma of the, apparently cured by adrenalin, 294
Eyesight, artificial light in relation to, 580.
Eye-strain, detection and relief of, 862

F.

Facial paralysis, rare symptoms in peripheral, 425.
Faith healing, Supreme Court opinion on, 824.
Family physician of the past, present, and future, 446.
Fanoni, Antonio, syphilis in the barber shop; a case of infection through an accidental razor wound, 936.
Fatty acids in water, 24; degeneration, 345.
Fecundity, instances of, 221, 225.
Fee question, the patient and the, 138.
Feeding, forcible, 280.
Femur, rare fracture of the lower end of the, 595.
Fever, should it be treated? 741; slow continuous, 947.
Fibroid tumors, opinons of surgeons and pathologists as to the origin and cause of, 323; supravaginal amputation of uterine, 954.
Filaria, life history of the, 344; medinensis, 910.
Filariasis cured by operation, 516.
Fingers, infected, 320.
Finger-tips, reconstruction of, by sponge education, 184.
Finsen-light treatment, 187, 599; of smallpox and various dermatoses, 714.
Fire department, pay of surgeons to the, 18.
First-aid instruction to railway employees, 299; packet for military use, 197.
Fischer, Louis, summer disorders, dietetic management and milk substitutes in children, 169.
Fisher, William R., some popular objections to vaccination, 91.
Flat foot, apparatus for, 236.
Fly as a bearer of disease, 480.
Fœtus, death of the, potassium chlorate in the prevention of, 352.
Food adulteration, testing, 743; chemical preservatives in, 180; emergency, 580; laws, 298; poisoning, 189.
Foot-and-mouth disease in New England, 903.
Football, strenuous, 699.
Footprint records, 348.
Forceps, use and abuse of the obstetrical, 591.
Foreign bodies in the digestive tract, 507.
Foreign service medical corps in the U. S. Army, 902.
Foster, Hal, the subcutaneous use of paraffin in deformed noses, with the report of a case, 595.
Fourth disease, 344.
Fracture, a rare, 144; in the newborn, etiology and diagnosis of, 344; massage in the treatment of, 624; the lower end of the femur, a rare, 595; of the lower extremities, tenotomy in, 467; of the posterior tarsal bones, 471; of the superior maxilla, 388; of the tibia and fibula, ultimate results of, 508; pulmonary embolism following, 66; through the site of an excised knee-joint, 233; treatment of, 63; ununited, 1036; ununited, due to osteomyelitis, 748; value of detailed diagnosis in, 1037.
France, infant mortality in, 760; medical graduation of foreigners in, 189; temperance question in, 858.
Franklin, Milton, the *x*-ray, 652.
Freudenthal, W., some hints to the general practitioner on the treatment of chronic nasopharyngeal catarrh, 211.
Frontal sinus, treatment of suppuration in the, 140.
Fulton, John S., the plague in San Francisco, 905.
Fumigation, methods of, faulty, 800.

G

Gallant, A. Ernest, a new bivalve uterine drain for the treatment of uterine retention and sterility, 836.
Gall-bladder, diseases of the, 512; indications for extirpation of the, 871; removal of, by Finney's method, 60; removal of, through a lumbar incision, 552.
Gallstones, operation for, 393; pancreatic disease in relation to, 947; simulating cancer, 23; surgery of, 676, 1033.
Ganglionic fever, 187.
Gangrene following subcutaneous infusions, 751; following typhoid fever, 1013; hospital, relation of proteus infection to, 949; symmetrical diagnosis of, from endarteritis obliterans, 906.
Garrigues, L. F., some varieties of surgical tuberculosis, with special reference to a new method of treatment, 285.
Gas, dangers of illuminating and fuel, 993; effect of leakage of, upon the public health, 37; poisoning, chronic, 387.
Gas-bacillus infection, 872.
Gasser, Herman, sensation and volition, 567.
Gasserian ganglion, excision of the, 667.
Gastritis, experimental, 709.
Gastroenterostomy, complications, following, 32, 307; McGraw's method of, 870; the circulus vitiosus following, 949.
Gastrointestinal disease, hydrotherapeutics in, 414.
Gastrojejunostomy in gastroptosis, 758.
Gastropathies of static origin, 948.
Gastroptosis, omental hammock for, 627; surgical treatment of, 194.
Gastrorrhaphy for gunshot wounds, purse-string suture in, 782.
Gelatin, tetanus from subcutaneous injections of, 268; tetanus spores in, 920.
Genitourinary therapeutics, 987.
Germany, therapeutics in, 972.
Germ-diseases, non-microbian, 736.
Gestation, ectopic, etiology, diagnosis, and treatment of, 351; intraperitoneal hemorrhage incident to ectopic, 830; repeated ectopic, 801.
Giantism, 896.
Gibson, Axel E., relation of consciousness to the nervous system, 812.
Gilbert, J. Allen, a case of multiple personality, 207, 354.
Girlhood, pubescent and adolescent periods of, 416.
Glanders, human, 787; the poison of, 268.
Glaucoma, causes of primary, 785; post-operative history of fifty cases of, 521; sympathectomy for, 571.
Gleitsmann, J. W., subglottic sarcoma removed endolaryngeally with galvanocautery snare, 12, 112.
Glioma of the nerve centers, 438.
Glycerophosphates, 517.
Glycosuria, relation of oxaluria to, 946; suprarenal, 786.
Goelet, Augustin H., a study of the indication for nephropexy, 969; making and closing the median cœliotomy wound, 566.
Goiter, operative treatment of, 516.
Gonorrhœa, antiseptic packing for, 625; auto-infection after, 373; instructions to patients affected with, 975; irrigation treatment of, 1028; paralysis complicating, 589; silver vitellin in the treatment of, 494, 574; systemic character of, 961, 995; the curse of, 869; urticaria in, 711.
Gorgas, W. C., discussion of the report on yellow fever on the U. S. Ship *Plymouth* in 1878 and 1879, 530; mosquito work in Havana, 81; thanks of the president of Cuba to, 501.
Gout, hepatic, 144; in the United States, 708; pharyngeal, 27; quinic acid in, 226.
Graves' disease, Raynaud's disease in a patient with, 575.
Griffin, E. Harrison, what can be done to prevent the spread of syphilis, 1003.
Griffith, Frederic, an instrument to increase the scope of cocaine surgery, 357.
Grossmann, L. W., hysterical (?) hemiplegia, 595.
Grubbé, Emil H., *x*-rays in the treatment of cancer and other malignant diseases, 692.
Guam, leper colony in, 262.
Guitéras, Ramón, the diagnosis of surgical diseases of the kidney accompanied by pyuria, 721.
Gunshot wounds of the intestine, 449;

of viscera, importance of drainage of, 28.
Gynecology, electrotherapeutics in, 51; importance of an apprenticeship in operative, 554; medical, 673.

H

Hæmatemesis, pathogenesis of, 382; post-operative, 388; prognostic significance of, 600; treatment of, 80.
Hæmaturia, fulminating tropical, 106; idiopathic or congenital, 119.
Hæmoglobinuria, 225; carbonyl, 387; quinine idiosyncrasy leading to, 68.
Hæmolysis in heterogeneous serum, 830; influence of alcoholic intoxication upon, 550.
Hæmolytic serum, 751; origin of the active principle of, 880.
Hæmophilia, treatment of, 713; with symptoms of defective circulation, 507.
Hæmophiliac, death of a, after removal of the tonsils, 862.
Hæmoptysis, peculiar complication of, 671; treatment of, 23.
Hæmostasis, electrothérapeutic, 103.
Haig, A., the prominent eye, its meaning and clinical association, 561.
Hair-balls in the stomach, 947.
Hall, J. N., two cases of bronchial obstruction in phthisis; two cases of rheumatic creaking in the shoulder-joint in phthisis; two cases of thrombosis of the common iliac vein after typhoid fever; embolism of the bifurcation of the aorta, 149.
Hallucinations and illusions, 420.
Halstead, A. E., inflammation and perforation of Meckel's diverticulum as a cause of septic peritonitis, with a report of two cases of typhoid perforation of Meckel's diverticulum, 849.
Hand, claw, operative treatment of, 236.; dangers of dirty, 835; disinfection of the, 796.
Handshaking, dangers of, 979.
Hanot's disease, gastric digestion in, 711.
Hardenbergh, Daniel B., vacation courses for post-graduate study in Berlin, 63.
Harrison, B. D., medical reciprocity, or interstate exchange of licensures, 522.
Harlem Medical Association, 505.
Harris, George R., resection of nearly eightfeet of gangrenous intestine; recovery, 563.
Harris, Searle, the early diagnosis of pulmonary tuberculosis, 608.
Harvard, chair of comparative anatomy at, 856.
Havana, eradication of yellow fever from, 648, 702; health of, 582; mosquito work in, 81; quarantine against yellow fever in, 781; sanitary condition of, 941.
Hay fever, immunizing treatment of, 114; successful treatment of, 266.
Hayes, F. M., hypertrophic rhinitis and its sequelæ, 253.
Hay's test for bile in the urine, 465.
Head, injuries of the, 223.
Headache of nasal origin, 187.
Hearing of school children, 541; theory of cross education in, 865.
Heart, aneurysm of the, 948; atresia of the conus pulmonalis, 591; clinical notes on diseases of the, 429; concentric hypertrophy of the right ventricle, 24; digitalis and aconite in diseases of the, 425; disease of, in children, 388; disease of the muscle of the, 270; treatment of diseases of the, 428; effect of exercise upon the, 505; functional power of the, 346; gunshot wound of the, 910; in diphtheria, 630; in old age, 591; massage of the exposed, 787; medical gymnastics and massage in diseases of the, 347; musical murmurs, 786; nervous affections of the, 950; nervous system in relation to the, 751; penetrating wound of the, 749; pleural effusions in diseases of the, 864; rupture of the, 429; suture of the, 390, 703, 846; tobacco, 184; treatment of simple weakness of the, 358; tuberculosis of the, 630; the aneurysms in the, 507; unusual murmur of the, 995; wandering, 146.
Heart-stroke, 314.
Hebephrenia, 755.
Hedges, E. W., a misplaced appendix, 594.
Hemianæsthesia, psychical element in hysterical, 471.
Hemicrania, periodicity of, 320.
Hemiplegia, hysterical, 595; infantile cerebral, paradoxical pseudohypertrophy following, 896.
Hemorrhage, concealed accidental, 988; control of emergency, 712.
Henoch's purpura, 269.
Heredity, acquired characteristics not transmitted by, 144; and biogenesis, 763; in gastroenteric disturbances, 25; physical basis of, 137; some statistics regarding, 599.
Hernia, congenital factor in, 900; inguinocrural, of the cæcum, 389; inguinal interstitial, in a woman, 875; inguinosuperficial, 874 local; anæsthesia in operations for, 677; lumbar, 1029; of the liver into the umbilical cord, 703; ovarian cyst in, 875; medical treatment of, in Arabia, 896; medical treatment of umbilical, 624; strangulated, in a woman ninety years old, 950; strangulated, in infants, 677; treatment of gangrenous bowel in strangulated, 630; treatment of umbilical, 297; vaginal, 644; varicose aneurysm of the saphena magna mistaken for, 590.
Herpes zoster, prevalence of, 709.
Heterogenesis, 498.
Heterophoria, partial or graduated tenotomy in, 303.
Hetol in tuberculosis, 947.
Hiccough, treatment of, 520, 616.
Hiers, J. Lawton, malarial infection a potent factor in asthenopic conditions, 572.
Hill, L. L., a report of a case of successful suturing of the heart, and table of thirty-seven other cases of suturing by different operators, with various terminations and the conclusions drawn, 846.
Hip, congenital dislocation of the, bloody operation for, 471; congenital dislocation of the, Lorenz operation for, 306, 658, 977; treatment of congenital dislocation of the, 235.
Hip-disease, diagnosis of, 233.
Hodgkin's disease, 41, 669; a hard variety of, 878.
Hopkins, George G., phototherapy of tuberculosis, 860.
Hopkins, George W., superheated compressed air in the therapeutics of chronic catarrhal otitis media, 396; contest over the possession of a, 383.
Hospital construction, essentials of modern, 32; management, bane of politics in, 739.
Hospitals, chronic cases in, 265; medical representation in the management of, 507; need of new, in New York, 461; well-to-do patients in, 623.
Hospital Graduate Club, 62.
Hot-air, compressed, in the treatment of chronic catarrhal otitis media, 396.
House furnishings, unsanitary, 821.
Huber, John P., the mysteries of life and mind, 251.
Hunchback, forcible traction for, 173.
Hunter, J. Dickson, the treatment of acute dysentery, 731.
Hunter, John, some points in practical surgery suggested by the study of the life and work of, 616.
Hydatid cysts of the lung, 591; scattering of, by operation, 787.
Hydræmia, malaria in relation to, 695.
Hydrocephalus, partial internal, 157.
Hydronephrosis, intermittent, nephrectomy for, 343.
Hygiene, progress in public, 656.
Hyoscine in morphine addiction, 952; in the treatment of drug habits, 848.
Hyperpyrexia, cases of, 863.
Hypnotism, abuse and control of, 980.
Hypodermic case, a pocket, 319.
Hyponomoderma, 551.
Hysterectomy, abdominal, 30; total abdominal, for fibromyoma uteri, 351.
Hysteria, abdominal section in, 352; and organic disease, 441; following traumatism, 345; major differentiation of, from organic disease, 156; spinal reflexes in, 305; syphilitic, diagnosed surgically, 107; therapeutic value of work in, 142.

I

Ice-cream, danger in, 616, 905.
Icterus, early diagnosis of, 670, 1029; epidemic, 863; fetal, 185; gastric digestion in chronic, 711; gravidítatis, etiology of recurrent, 148; hereditary recurrent attacks of, 176; influence of thyroid medication on the jaundice of, 306.
Idiocy, obstetrical aspects of, 630.
Ileus, treatment of, with belladonna, 96.
Iliopsoas muscle, contraction of the, as an aid to diagnosis of the contents of the iliac fossa, 144.
Illinois State Board of Health, minimum requirements for medical colleges recognized by the, 439.
Illusions and hallucinations, 420.
Immigration, menace of, to the national health, 179, 740.
Immunity, 80, 148, 670, 706; organotherapy in relation to 671; present ideas of, 832; quantitative relations of the various factors in, 509.
Immunization, studies in, 911.
Impetigo, Bockhart's, 629.
Incompatibilities, 147.
Incontinence of urine, silver nitrate in nocturnal, 864.
Incubator, a human, 360.
Indian Tribe, extinction of a once powerful by disease, 1023.
Inebriety, early stages of the disease of, 649.
Infant feeding, review of the older writings on, 632; percentages in 76.
Infant food, buttermilk as, 468.
Infantile paralysis, arthrodesis of the ankle for, 232, 303; epidemic of, 232, 986.
Infantilism, 278.
Infant mortality, 939, 940.
Infants, sterilized linen for, 786.
Infatuation, epidemic, 769.
Infectious diseases, alcohol in the treatment of, 143; management of circulatory failure in, 74.
Influenza, cases of, 1027; cause of cardiac irregularity in, 784; epidemic streptococcal, 320; mental disorder secondary to, 344.
Infusion through the umbilical vein, 160.

Inhalation of fluids into the deeper portions of the lungs, 671.
Insane, care of, in New York State, 657; convalescent, 437; improvement of the condition of the, 624; international conference on improving the conditon of the, 422; State hospitals for the, places for young medical men in, 855; treatment of the, in private practice, 709.

Philippines, health matters in the, 382, 460, 820; saving of life in the, 99.
Phlebitis of the ophthalmic vein and of the cavernous sinus following a dental abscess, 470; pathogenesis of, 471.
Phloridzin test of renal insufficiency, 945.
Phobias, 861.
Phthisical disposition, diagnosis of the inherited, 468.
Phthisiophobia, 630.
Physician, a good, 479.
Physician and his bill, a, 1023.
Pigments of the organism, 25.
Pistols, wounds caused by automatic, 199.
Placenta prævia, early recognition and treatment, 546; statistics of, 321.
Plague, agglutination of the bacillus of, 389; as a soil infection, 345; campaign against, in the Punjab, 700; chronic, in rats, 452; in Batoum in 1901, 270; in New York harbor, 1023; in Odessa, 704; in San Francisco, 501, 702, 774, 792, 905, 1022; inoculation against, on a large scale, 742; national conference on the, called for, 902; present-day knowledge of, 911; rats in relation to the, 669; report on, 703; serum treatment of, 506; vaccination against the, by way of the stomach, 431.
Plasmodium of malaria, 916.
Pleura, primary new growths of the, 761.
Pleural exudation, an early sign of, 695.
Pleurisy in typhoid fever, 945; postoperative, 224; tuberculous, 514.
Pleuritic effusion, a fluorscopic and percussion sign of, 266.
Plymouth, yellow fever on the, in 1878 and 1879, 530.
Pneumatosis gastrointestinalis, 56.
Pneumonia, 755, 827; apyretic, 148; clinical aspects of, 978; complications and sequelæ of croupous, 386; creosote in, 601; diagnosis of, in young children, 147; disappearance of the patellar reflex in, 389; due to Friedlander's bacillus, 909; endocarditis as a complication of, 667; hydriatic treatment of, 111; in children, 77, 950; inflammation of the diaphragm complicating, 563; intestinal autointoxication simulating, 630; leucocyte chart in, 456; lobar, in young children, 184, 591; loss of the patella reflex in lobar, in children, 268; opium dangerous in, 359; peripheral venous thrombosis in, 107; physiological pathology of the circulation in acute, 110; pythogenic, 588; serum treatment of, 22; sodium salicylate in, 782; symposium on, 713; treatment of, 27, 64.
Pneumonic infection, general, in a young child, 863.
Pneumothorax, remarkable case of, 750; spontaneous, 990; spontaneous non-tuberculosis, 269.
Poliomyelitis, epidemic, 528.
Politics and public charity, 419.
Polk, Wm. M., operations on the uterine appendages for sterility, 881, 912.
Polyarthritis, chronic, 96.
Polyhydramnios, 342, 667.
Polymyositis, acute hemorrhagic, 505.
Polyposis, intestinal, 188.
Pooley, Thomas R., two unusual complications following cataract extraction (1) death after cataract extraction from diabetes; (2) delirium tremens following extraction of cataract.
Pork pie, poisoning by, 624.
Porter, William Henry, rational or dietetic treatment of Bright's disease, contrasted with surgical intervention, 481.
Porto Rico, climate of, 429; vaccination in, 899.
Post-graduate study in London, 857.
Postpartum hemorrhage, use of the tampon in, 224.
Pott's disease, double, 232; final results of the treatment of, 233; forcible traction in the deformity of, 173.

Practitioners' Society of New York, 70, 912, 995.
Precipitins, formation of the specific, of Krause, 711.
Pregnancy, abdominal section during, 556; appendicitis complicating, 427; autointoxications of, 904; cancer of the uterus, complicating, 230; extrauterine, 306, 671, 859; extrauterine, twice in the same woman, 798; hemorrhage into the spinal cord in, 391; hygiene of, 93; intrauterine fibroids complicating, 555; leucocytosis in, 345; ovariotomy during, 831; repeated extrauterine, 801.
Prescribing, unscientific and careless, 913.
Presenility, neurotic indications of, 499.
President Roosevelt, injury to, 543; the physician of, 339.
Pressure paralysis in vertebral disease, 236.
Prince Edward Island Medical Society, 300.
Pritchard, William Broadacre, a classical example of Landry's paralysis, 136.
Prize, Alvarenga, of the College of Physicians, 662; award of the Nobel, 903; for essays on ichthyotoxismus, 857; for essays on preventive medicine, 743; for essays on tropical medicine, 857; for plans for tuberculosis sanatoria in England, 300; for the prevention of pneumonokoniosis, 902; of the Berlin Academy of Sciences, 623.
Professorship, a disputed, 339.
Prognosis, the question of, 257.
Prostate, extirpation of the, for senile enlargement, 393; hypertrophy of the, 868, 946; light treatment of hypertrophy of the, 550; perineal route superior to the suprapubic in surgery of the, 29; recent progress in the surgery of the, 145; removal of the, through the perineum, 516; tuberculosis of the, 64; treatment of hypertrophy of the, 909.
Prostatectomy, cases of, 385; intrapubic section for, 667.
Prostatitis, symptoms and course of acute catarrhal, 719.
Prostitution, licensing of, 339; prophylaxis of venereal disease in relation to, 517.
Pruritus ani, 184; ani, heat in the treatment of, 103; faradization in the treatment of localized, 470; jaundice, influence of thyroid medication on, 306; vulvæ, surgical treatment of, 319.
Pseudocyesis, ovarian irritation as a factor in the etiology of, 65.
Pseudoepilepsies, thyroid treatment of, 158.
Psittacosis infection, 668.
Psoriasis inherited (?) from a myxœdematous person, 908; pathogenesis of, 226.
Psychic therapeutics, use of, by the general practitioner, 493.
Psycopathies, anxious, 432.
Pterygium, modern, treatment of the, 224.
Ptosis, post-grippal, 590.
Puberty, psychoses of early, 420.
Public Health and Marine-Hospital Service, creation of the, 61, 183.
Publishing house, evolution of a medical, 500.
Puerperal eclampsia, 749; eclampsia, thyroid extract in, 669; fever, serum treatment of, 225.
Puerperium, leucocytosis in, 345.
Pulmonary tuberculosis (see also *Consumption* and *Tuberculosis*), army sanatorium for, in New Mexico, 197; arsenic subcutaneously in, 468; causation of, 217; climatic treatment of, 47; creosote and guaiacol in the treatment of, 932; diet in, 981; early diagnosis of, 608; in the Navy, 628; influence of, on the nerves and senses, 469; influence of the micrococcus tetragenus upon, 786; inoperable nature of the lesion of, 545; "klopfen" treatment of, 147; milk infection in, 946; mission of societies for the prevention of, 96; oil massage in, 710; operative treatment of, 990; pathology and curability of, 496; quantitative changes in the blood in, 133; recognition of, at the apices, 467; sanatorium treatment of, 469; shape of the thorax in, 136; surgery in relation to, 14; symposium in, 752; syphilis of the lung simulating, 926, 952; treatment of, 388; urea in the treatment of, 908, 1020.
Pulmonary valve affections, 428.
Pulp, tooth, evolution of the, 224.
Pulse at an elevation of 10,200 feet, 495; irregular, in cardiopathic states, 26.
Punton, John, the criminal responsibility of the epileptic, 765.
Pupils, inequality of the, in thoracic aneurysm, 145; reaction of, to light in new-born cats, 226.
Pure food laws, 298.
Purpura fulminans following scarlet fever, 267; hæmorrhagica, infectious origin of, 304; Henoch's, 269.
Pus tubes, ruptured, 553.
Pyloroplasty, new method of, 33.
Pylorus, palpation of the, 830; stenosis of the, 786.
Pyometra in a uterus bicornis puerperalis, 469.
Pyosalpinx, 783; and appendicitis, 798; on top of the fundus uteri, 953.
Pyuria, diagnosis of surgical diseases of the kidneys accompanied by, 721.

Q

Quacks, condemnation of, in London, 826; Australia, 138.
Quarantine, clinical thermometer as an aid in inspection, 690.
Quinine, fluorescence of, 26; poisoning by, 151.
Quintuplets, a case of, 480.

R

Rabid dogs, disposal of, 299.
Rabies, development of, after protective inoculation, 549; latent for twenty months, 23.
Radial artery, hæmatoma of the sheath of the, 202.
Rafferty, H. N., the etiology of relapse in typhoid fever, 1014.
Railway injuries, primary treatment of, 407.
Railways, ambulance cars on, 221; sanitation on Mexican, 991.
Ranney, A. L., the eye factor in seasickness and other types of vertigo, 707.
Rattlesnake bite, a case of, 151.
Ray, J. Morrison, penetrating injuries of the eye, with or without the presence of a foreign body in the organ, and their treatment, 129.
Raynaud's disease, case of, 117; diagnosis of, from endarteritis obliterans, 906; hysterical, cured by suggestion, 25; in a patient with Graves' disease, 575; treatment by the tourniquet to counteract the spasm in, 858.
Reciprocity in medical licensure, 522, 663.
Recreation and overwork, 420.
Recruit, considerations regarding the, 196.
Rectum, abdominal approach to tumors of the, 30; cancer of the, 756; excision of cancer of the, 506; treatment of stricture of the, 756, 987.
Red Cross, international conference of the societies of the, 61.
Reflex action, autointoxication in relation to, 937.
Reflex, infraspinatus, 626; mechanism of the plantar, 157.
Reflexes, spinal, in hysteria, 305; varieties of, 438.
Relapsing fever, etiology of, 160.
Renal disease, ocular expressions of, 111; insufficiency in the tropics, 827.
Respiration at an elevation of 10,200 feet, 495; bucconasal, 147.
Respiratory diseases, electric light in, 104.
Retina, genesis of glioma of the, 949; hemorrhage of the, subconjunctival injections of sodium chloride in, 590; rupture of the, 912.
Reyburn, Robert, causes of cancer, 171.
Rheumatic children, management of, 73.
Rheumatism, acute articular, 342; bacteriology of, 307; differential diagnosis of acute polyarticular, from a surgical standpoint, 65; early diagnosis of attacks and relapses of, 960; excision of the knee for chronic, 649; hæmatology of, 303; hyperpyrexia of, 186; immunity in relation to, 387; obstinate subacute, 952; parasitology of acute, 698; pathogenesis of acute articular, 146; serum treatment of, 22, 381, 737; venous thrombosis in acute articular, 146.
Rheumatoid arthritis, 452; treatment of, 908.
Rhinitis, hypertrophic, 253.
Rickets, congenital, 949; pasteurized milk as a cause of, 1016; surgery of, 624.
Ringworm contracted from a cat, 828.
Robinson, Beverley, a case of angina pectoris with autopsy, 964, 996.
Rockwell, A. D., the neuron theory; its relation to physical and psychical methods of treatment, 933.
Röntgen rays, 652, 715; action of, on living tissue, 828; dermatitis from, 106, 267; in cancer, 97, 193, 267, 385, 473, 667, 692, 715, 757, 762, 798, 921; in cancer of the larynx, 113, 602, 945; in sarcoma, 34, 506; in skin diseases, 97, 265; in the diagnosis of brain tumor, 547; in ulcer of the leg, 668; medicolegal value of the, 202; stereoscope, 233; suit for burns from, 702; therapeutic uses of the, 224, 472, 474, 517, 1007.
Rome, improved sanitary conditions in, 720.
Rosenberg, Daniel Davis, quinine poisoning, 151.
Ross, Roland, award of the Nobel prize to, 903; services and reward of, 375.
Round ligaments, extraperitoneal anchorage of the, 872.
Rowing for women, 616.
Rubella scarlatina, 1027.
Ruminating family, 346.
Rural districts, sanitary protection for, 413.
Russell, Howard C., hyoscine in the treatment of drug habits, 848.

S

St. Petersburg, Imperial Military Medical Academy of, 70.
Saliva, diagnosis by means of the, 115.
Salpingitis, suppurative, 956.

Salt, effect of lack of, upon the organism, 786.
Sand, intestinal, 225.
Sanitary protection for rurual districts, 413.
Sarcoma, arsenic for, 966; cataphoric diffusion for, 466; electric sterilization of, 466; multiple, 515; of the sixth nerve, 913; subglottic, removal endolaryngeally, 12, 112; x-ray treatment of, 34, 506.
Scapula, elevated, 231; excision of the, with presentation of the arm, 910; fracture of the, 1036.
Scarlatina after operation on the throat, 834; associated with erysipelas, 469; five attacks of, 751; hæmorrhagica, 304; microscope in the diagnosis of, 945; purpura fulminans following, 267; relapse of, 946; serum treatment of, 543, 742.
Schauffler, William Gray, a new stain for diphtheria bacilli, 895; the American School of Medicine at Beyroot, 1026.
Schmitt, J. A., diagnosis of incipient carcinoma of the endometrium, 175; the surgical treatment of chronic Bright's disease, 401.
School life, evil effects of, on girls, 372.
School-teacher and the doctor working in harmony, 614.
Schools, health in, 661, 822.
Sciatica, treatment of, 119, 148, 239.
Scissors, preventing the click of, 357.
Sclerodema, generalized, 633.
Sclerœdema, 785.
Sclerosis, amyotrophic lateral, 388; disseminated, causing ocular palsies, 153; multiple, diagnosis of, of, 634; posterolateral, spinal, 155.
Scurvy, origin of, 748; sterilized milk as a cause of, 1016; prevention of, 627; time required to produce, by inappropriate food, 467.
Seasickness, 594; age factor in, 707; relation of, to vertigo, 748.
Self-accusors from the medicolegal point of view, 436.
Senilism, 278.
Sensation and volition, 567.
Sensibility, monoplegic disturbances of, in cortical paralysis, 809.
Septicæmia, meningococcus, 909.
Septic infections, effect of rest upon, 387.
Serratus magnus, paralysis of the, 117.
Serum, antistreptococcus, 831, 1029; diagnosis by means of, 550; hæmolytic action of normal, 509.
Sewage, report of the British commissioners, 759; treatment of typhoid-contaminated, 537.
Shears, George P., when and why does labor begin, 281.
Sheldon, John G., a case of peritonitis of unknown origin, 394.
Shiga's bacillus in relation to dysentery, 639.
Ship surgeons, 619.
Shock, avoidance of, by cocainization of the large nerve-trunks, 511; etiology of, 625.
Shoulder, amputation at the, in axillary cancer, 862; amputation for sarcoma of the, 515; creaking of the in phthisis, 149; round, 235, 782.
Sialorrhœa in general paralysis, 629.
Siam, climate and diseases of, 311.
Sierra Leone, typhoid fever in, 311.
Sigmoid flexure, false diverticula of the, 238; sinus, phlebitis of the, 960.
Sill, E. M., chlorosis in a child nine years old, complicated with estivoautumnal malaria, 395; pasteurized and sterilized milk as a cause of rickets and scurvy, 1016.
Silver vitellin in diseases of the nose, throat, and ear, 810; in gonorrhœa 494, 574.
Singers, changes in the form of the arytenoid cartilage seen in, 115.
Sinusitis, frontal, 738; sigmoid, 960; sphenoidal, 115; treatment of suppurative frontal, 140.
Sixth nerve, sarcoma of the, 913.
Skin, creeping larvæ in the, 551; dependence of diseases of the, upon upon nutritive disturbances, 749; idiopathic atrophy of the, 677; importance of diagnosis of diseases of the, 546; melanotic tumor of the, 390; rare diseases of the, 184.
Skinner, Clarence Edward, x-light in therapeutics, 1007.
Skull, repair of bony defects of the, by transplantation, 431.
Sleep, measuring, 220; normal, 752.
Sleeping sickness, condition of the central nervous system in a case of, 589; nature of, 936; notes on, 1028 suggestion as to the etiology of, 951.
Sloane Maternity milk set, 38.

Smith, A. Lapthorn, removal of the appendix, 63.
Smith, Frederick W., the hygiene of pregnancy, 93.
Smoke, problem of, 584.
Smoking, nicotine question in, 815.
Snake poisoning, studies on, 17.
Snakes, venomous, 578.
Soap tincture for sterilizing instruments, 478.
Sociology, some practical problems in, shown by a study of the Southern negro, 331.
Soil pollution and typhoid fever, 617.
Souchon, Edmond, on the transportation of mosquitos by vessels, 8; the eradication of yellow fever in Havana, 648; the mosquito on board of vessels at quarantined ports as a factor in the transmission of yellow fever, 256; the United States Public Health and Marine-Hospital Service, 182.
Southern Surgical and Gynecological Association, 868.
Specifics in the treatment of disease, 72.
Sphenoidal sinus, empyema of the, 115, 267.
Spinal anæsthesia, new method for, 1000.
Spinal concussion, 757.
Spinal cord, gunshot wound of the, 28; hemorrhage in the, in a bleeder, 901; sarcoma of the third cervical segment of the, 156; transverse lesion of the mid throracic segments of the, 155; tumors of the, 882.
Spinal localization, some points in, 154; paralysis, 746; spastic and syphilitic, 670.
Spine, extensive traumatisms of the, 757; lateral curvature of the, 235; surgery of the, 159; typhoid, 22, 143, 626, 966.
Spitting, drastic law against, 983.
Spleen, enlargement of the, with anæmia, 74; extirpation of a leucocythæmic, 34; extirpation of a pseudoleukæmic tumor of the 670; myelogenous changes in the, 305; rupture of the, 188, 864.
Splenectomy for leukæmic enlargement, 306.
Spondylitis following typhoid fever, 232; typhoid, 22, 143, 626.
Sponges found in operation wounds, 237.
Spotted fever of the Rocky Mountains, 143, 540.
Stammering, report of a case of, 114.
Static machines and condensers, report on, 472
Steatosis, latent hepatic, of alcoholics, 106.
Stenocardia, therapy and pathogenesis of, 785.
Sterility in women, cause and treatment of, 193; operations upon the uterine appendages for, 881, 912; relation of obesity to, 677.
Sterilization of women, artificial, 416.
Stevens, Martin L., quantitative changes in the blood in pulmonary tuberculosis, 133.
Stillborn, resuscitation of the, 559.
Stillman Infirmary at Harvard, opening of the, 543.
Stokes-Adams syndrome, 240.

Stomach, ablation of the, 510; acidity of the, 343; adenoma of the, developing from an ulcer, 1029; affection of the, simulating cancer, 831; atonic dilatation of the, 668; dilatation of the, 274; electrical reaction of the musculature of the, 124; fibromyoma of the, 237; gastrotomy for ulcer of the, 104; gunshot wound of the, 28; hairballs in the, 947; high-frequency currents in atomic dilatation of the, 710; latent cancer of the, with metastases, 864; non-malignant affections of the, treated by gastroenterostomy, 393; olive oil for ulcer of the, 997, operation for cancer of the, 678; operation for non-malignant disease of the, 678; pathogenesis of hemorrhage from the, 382; reason why self-digestion does not occur, 749; removal of a tube from the, 875; topical diagnosis of ulcers and tumors of the, 268; treatment of puerperal ulcer of the, 557; treatment of ulcer of the, 68; ulcer of the, 305, 815; uric acid in the blood as a cause for certain troubles of the, 828.

Stony Wold sanatorium, 383.
Strabismus, indication for operation in, 748.
Street, P. W., the glycerophosphates, 571.
Streets, bacteria in the, 662.
Streptococcal grippe, 320.
Streptococci, agglutination of, 784; antiserum for, 831; plurality of, 711.
Streptococcus pyogenes, relation of, to variola, 317.
Streptothrix, infection by, 905.
Strider, infantile, 632.
Subway works, insanitary condition of the, 339.
Suggestion, psychic, relation of, to electrotherapeutics, 477.
Suicide in France, 852; in Germany, 560; in the Russian Army, 1020; in the United States in 1901, 498.
Summer diarrhœa, leucocyte count in, 269; of children, 185, 223; of children, dietetic management of, 169; Shiga's bacillus dysenteriæ in, 417, 716, 915.
Sunlight in the treatment of tuberculosis, 681.
Sunstroke, 314; malarial fever mistaken for, 304; prophylaxis of, 548; treatment of, 551.
Suprarenal extract in Addison's disease, 440; glands, sugar controlling function of the, 709.
Surgeon, military, in Cromwell's time, 379; the rural, 191.

Surgery, a standard technique in operative, 712; contribution of pathology to, 512; teaching of, 31.
Surgical dressings, injury to young cells caused by, 96; technique, psychology of habit in, 428.
Swinburne, G. K., the use of argyrol in the treatment of acute gonorrhœa, 574.
Symmers, Douglas, acute intestinal autointoxication with symptoms resembling the onset of croupous pneumonia, 636.
Sympathectomy for glaucoma, 571.
Sympathetic, function of the cervical ganglia of the, 71; ganglion, submaxillary gland secretion after resection of the, 147.
Symphysis pubis, relaxation of, following normal labor, 547.
Syncytioma malignum, parasitology of, 240.
Syphilis, acute renal, 863; in relation to life insurance, 588; in the barber shop, 936, 986; instruction to persons affected with, 975; mistaken for smallpox, 907; preventing the spread of, 1003; pulmonary, 386; recrudescence of latent, after fevers, 640; relationship of, to the body politic, 752, 783; sequelæ of infantile, 106; treatment of, 590.
Syringomyelia, atypical, 117; pathological anatomy and pathogegenesis of, 270.

T

Tabes dorsalis, arthropathy of the vertebral column in, 749; glycosuria in, 590; removal of the cervical sympathetic for optic atrophy in, 71; some anomalous cases of, 186; treatment of, 307; with marked bulbar symptoms, 634; with multiple sclerosis, 154.
Talmey, Bernard S., gynecological electrotherapeutics, 51.
Tape-worm, diabetes caused by, 829.
Tarantula, alarming symptoms following the bite of a, 715.
Taste, fifth nerve in regard to, 540.
Tavel's salt-soda. solution, injurious effects produced by the subcutaneous injection of, 549.
Taylor, A. S., a convenient hypodermic case, 319.
Taylor, Elwin C., an amputating retractor, 357.
Teachers' College, new physical culture school for, 384.
Teeth, attachment of the, 224.
Temporal bone, toxæmia from suppuration in the, 80; venous system of the, and its relation to the complications of mastoid disease, 290.
Tendon transplantation, 103; transplantation for a paralyzed quadriceps femoris, 785; transplantation of the biceps femoris, 586.
Tenotomy, cases of, 303.
Teratoma simulating pelvic abscess, 954.
Testicle, excision of the lumbar lymph nodes and spermatic vein in malignant disease of the, 910; rhabdomyoma of the, 237; tuberculosis of the, 64, 392; use of an undescended, 393.
Tetanus, 104; Baccelli treatment of, 590, 855; creosote in the treatment of, 77; following abdominal section, 553; following vaccination, 193; serum treatment of, 226, 862; spores of, in commercial gelatin, 920; toxins of, 509; treatment of, 507, 786.
Tetany, 64, 76; in gastric disorders, 906.
Thallium, poisoning by, 906.
Therapeutic agents, official supervision of, 579.
Therapeutics, advancement in, 273; German, 972.
Thermometer, use of the clinical, in quarantine inspection, 690.
Thompson, J. M., some chronic pathological processes seated in the deep urethral region, involving the male sexual function and the nervous system, 245.
Thompson, S. W., a case of Reynaud's disease occurring in a patient suffering from Graves' disease, 575.
Thomsen's disease due to cerebral lesions, 629.
Thorax, unilateral pressure on the, as an aid to diagnosis, 669.
Throat, anæsthetic for short operations on the, 507; scarlet fever arising after operations on the, 834; some functional neurosis of the, 307.
Thrombosis of both femoral arteries, 23; of the common iliac vein after typhoid fever, 149; post-operative crural, 429; venous, in acute articular rheumatism, 146.
Thrombus of agglutinated erythrocytes, 911.
Thumb, melanosarcoma of the, 226.
Thymus gland, enlarged, 75; enlarged, sudden death in a case of, 909.
Thyroid gland, accessory, at the base of the tongue, 988; sarcoma of the, 185; tumor, bone metastases in, 509; tumors, classification of benign, 64.
Thyroidectomy, exophthalmic goiter after, 154.
Tics, 434.
Tobacco, heart trouble from, 184; use and abuse of, 391; white-wood cure of the habit, 230.
Toeplitz, Max, nasal disturbances in typhoid fever and their sequelæ, 451.
Tongue, appearance of the, in a case of ankylostomiasis, 68; depressor, a new, 503; diagnostic value of the, in disease, 245; working of the, in ankylostomiasis, 591.
Tonsillar infection, remote diseases arising from, 74.
Tonsils, ablation of the, 68; acute general infection through the, 113; death from bursting of an abscess of the, 548; lingual, 119; lingual, cough in hypertrophy of the, 189.
Tonsillotomy, 835.
Torticollis, mental 469.
Tousey, Sinclair, a table of the differential diagnosis of coma, with report of a case of fracture of the base of the skull, intracranial hemorrhage, and compression of the brain, diagnosed by symptoms alone, trephining, recovery, 732.
Towsend, Terry M., prostatic gonococcal auto-reinfections of the urethra, 373.
Toxæmia from suppuration in the temporal bone, 80; mixed, 430.
Toxins, intestinal, 120.
Trachoma, 36; in New York, 739; in the public schools, 221; new forceps for, 913; prevention and treatment of, 359.
Tragus, epithelioma of the, 718.
Transplantation by exchange, 908.
Traumatism, acroparæsthesia following, 711.
Tremor, post-hemiplegic intentional, 120.
Triangular cartilage, rubber splints in the treatment of curvature of the, 116.
Trichocephalus dispar, 146.
Trichophytosis, 708.
Tricuspid diseases, 428.
Trifacial nerve, cause of death in operations in the region of the, 343.
Trigger finger, case of, 910.
Tropics, health in the, 199; renal insufficiency in the, 827.
Trunecek's serum, 427.
Trusts, medical, 338.
Trypanosoma in man, 591, 896.
Tubercle, anatomical, 24.
Tubercle bacilli in the nail-dirt of children, 635; of exalted virulence in man, 994.
Tuberculin, diagnostic value of, 1028.
Tuberculosis and public action, 259 Berlin congress on, 699, 702; bovine and human, 9, 57, 388, 550; 570, 628, 698; bovine, commercial aspects of, 15; cancer associated with, 189; cancer in relation to, 989; Charity Organization Society committee for the prevention of, 222, 260; Congress, charter for a, 1023; dietetic treatment of, 506; dust, dirt, dampness, and darkness as etiological factors in, 334; epitrochlear ganglionic, 68; etiology of, 950; electric ozonation in the treatment of, 409; fingernails as a medium for the transmission of, 538; garlic in the treatment of, 216; genital, treatment of, 392; general, 918; germ infection in, 508; hydrotherapy in, 259; hypertrophic, of the intestine, 860; ileocæcal, 786; immunization of cattle against, 908; in public asylums, 820, 938; increase of, among negroes, 772; infection in, 337; inoculation, 710; intestinal, 100, 670; meningeal, prognosis of, 431; metabolism in, 990; of bones and joints, treatment of, 231; of liver, spleen, and bronchial glands, simulating gumma, 510; of the appendix, 269; of the cervical glands, treatment of, 945; of the heart and pericardium, 630; of the urinary tract, 489; omental, cured by simple laparotomy, 471; operation for renal, 910; osseous, malignancy of, 231; peripheral neuritis in, 345; peritoneal, 74, 456, 557; peritoneal, medical treatment of, 358; peritoneal, operative treatment of, 226; phototherapy of, 860; present state of our knowledge concerning, 625; production of immunity against, in cattle, by Jennerization, 852; prognostic value of the diazo reaction in, 800; prostatic, 64; renal, operative treatment of, 226; results of sanatorium treatment of, 514; rôle of the lymph ganglia in protection from, 306; sanatoria for, in New Jersey, 190; sanatorium treatment, 736; serum diagnosis of, 226; serum treatment of, 190; sodium cinnamate in the treatment of, 145, 947; squabble between Koch and Garnault, 298; State in its relation to, 792; sunlight in the treatment of, 681; surgical treatment of peritoneal, 33; symposium on, 752; tent life in the treatment of, 907; testicular, 64; urea in the treatment of, 750; uterine, 954; varieties of surgical, 285; Vermont society for the study of, 621; war against in Paris, 1,023
Tumors, vascular, hot-water injections in, 945.
Turbinated body, bony cysts of the middle, 188.
Typhoid bacillus, chemical nature of the, 833; differentiation of, from the colon and dysentery, 469; in urine, 106; specific substances in, 186, 187.

Typhoid-colon group of bacilli, infection by the, 668.

Typhoid fever, 457; an outbreak of water-borne, 863; angina in, 23; at Chickamauga, 199; bacilli in the blood in, 852; bacilli in the sputum in pulmonary complications of, 863; castor oil in the treatment of, 755, 920; curative serum for, 347; diet, drugs, and diagnosis in, 161, 302; diet in, 829, 839; diseases of the ribs following, 873; etiology of, 303; factors in the spread of, 994; fecal impaction in, 188; from sources other than the water supply, 121; gangrene following, 1013; in children, 73, 749; in rural districts, 417; infection of ovarian cysts during, 864; inoculation against, 460; localized peritonitis in, 66; mammary abscess following, 508; nasal disturbances in, 451; neuritis complicating, 303; operation for perforating ulcer, 517; pathogenesis of, 629; paralysis of the pharynx following, 151; paralysis of the ulnar nerve following, 187; perforation of the bowel in, 68, 875, 896, 950; pleurisy in, 945; pneumonia complicating and diphtheria following, 347; prevalence of, 500; relapses of, 269; 1014; sewage disposal in relation to, in India, 1022; significance of abdominal pain in, 936; simulating puerperal sepsis, 1027; soil pollution in the spread of, 617; spondylitis following, 232; spread of, 793, 1026; surgical features of, 466; symposium on, 679, 832; symptomatology and diagnosis, 807; thrombosis in, 988, 1017; treatment of, 146; without intestinal lesion, 508.

Typhoid spine, 22, 143, 626, 966.

U

Ulcer, duodenal, 556; etiology, pathogenesis, and bacteriology of simple, 107; gastric, 305, 815; gastrotomy for recent gastric, 104; olive oil in gastric, 997.

Ulcers of the leg, treatment of, 79, 336; of the leg, *x*-ray and brush discharge in, 668; treatment of corneal, 25; treatment of gastric, 68; treatment of perforated gastric, 557; vesical, 143.

Ulnar nerve, division of the deep branch of, in the hand, 630.

Umbilical cysts, 24; due to tuberculous peritonitis, 75; hernia, operative treatment of, 297; hernia, radical treatment of, 624.

Uncinariasis, 144.

Upson, Charles R., dust, dirt, dampness, and darkness as etiological factors in tuberculosis, 334.

Uræmia, a consideration of, 303; aphasia from, 624; treatment of, 25, 430.

Urea in the treatment of pulmonary tuberculosis, 908, 1020.

Ureteral catheterism, 756.

Ureters, compression of the, by a fibroma of the uterus, 146; diagnostic and therapeutic value of catheterization of the, 466.

Urethra, antiseptic packing for inflammation of the male, 625; cancer of the, in women, 189; impacted calculis of the, in a young boy, 39; plastic surgery of the female, 265; prostatic gonococcal autoreinfection of the, 373; some clinic pathological processes in the deep, involving the male sexual function and the nervous system, 245.

Uric-acid bothers, 907; Cook's method of estimating, 40; in the blood as a cause of certain stomach and intestinal troubles, 828.

Urinary organs, nervous irradiations in the region of the, 711; tract, tuberculosis of the, 489.

Urine, first, of the newborn, 671; from each kidney, 641.

Urticaria, gonorrhœal, 711

Uterine adnexa, nervous crises following removal of the, cured by massage, 864.

Uterus bicornis puerperalis, pyometra in a, 469; bivalve drain for the, 836; cancer of the, 183, 558; cancer of the cervix complicating labor, 346; cancer of the, electrocautery clamp in the treatment of, 876; cancer of the, in the Mississippi Valley, 758; conservative treatment of inflammation of the adnexa, 120; early diagnosis and treatment of cancer of the, 143, 175, 193; electrical treatment of, prior to myomectomy, 953; fibroma of the, compressing the ureters, 146; fibroma of the, in a young child, 470; inversion of the, complicating polypus, 954; management of fibroids of the, 673; multiple fibroids of the, 265; operative treatment of prolapse of the, 352; prolapse of the, 873; purulent infiltration of the cervix, 306; retroflexed, clinical significance of a, 306; rupture of the, in the early months of pregnancy, 550; transplantation of the round ligaments for displacements of the, 871; treatment of fibroids of the, 353, 759; tuberculosis of the, 954; tumors of the, 956; vaginal operations for retrodisplacements of the, 376; vaginal route for operations on the, 552; *x*-rays and ultraviolet light in cancer of the, 921.

Uveitis, 505.

V

Vaccina, etiology of, 516; generalized, 66; microorganism of, 479; second eruption in, 430.

Vaccinal eruptions, 861.

Vaccination, 266, 577; accidental, 625; cause of sore arm after, 192; cheloid in the scars of, 589; complications of, 105; cost of neglecting, 624; efficiency of recent, 104; eruptions following, 427; from all points of view, 218; in New York City, 37; in Porto Rico, 899; in schools, 547; in the United States, 979; law regarding, sustained, 101; league in Great Britain, 182; legislation regarding, 737; some clinical aspects of, 784; some popular objections to, 91; tetanus following, 193.

Vaccine, experiments with filtered, 317; glycerinated, 16; production and control of, 788.

Vagina, atresia of the, 638; atresia of the, with no uters, 429; bacteria of the, in health, 673; myoma of the, 304.

Vaginal counter-pressure director, 955; route in operations on the uterus, 625; section, scope of, 955.

Valentine, Ferd. C., educational limitation of venereal diseases, 734; the urine from each kidney, 641.

Van Zandt, I. L., statistical report on creosote in pneumonia, 601.

Varicocele, 603.

Varicose veins, operative treatment of, 545.

Variola, see *Smallpox*.]

Veeder, M. A., typhoid fever from sources other than the water supply, 121.

Veins, air in the, 551, 948; therapeutic injections in the, 864.

Venereal disease, educational limitation of, 734; marriage in respect to, 24; prevention of, 18 517; treatment of, in garrison, 199.

Venous hum in relation to the blood count, 914.

Ventilation, dangers of lack of, 741

Ventroscopy in vaginal cœliotomy, 371.

Verbal obsessions, 304.

Vermont Society for the Study and Prevention of Tuberculosis, 621.

Vertebræ, laminectomy for fracture-dislocation of the fourth and fifth cervical, 757.

Vertigo, nasal, simulating epilepsy, 344; ocular, 748; psychical, 78; relation of seasickness to, 748.

Vincent's angina, 106.

Vineberg, Hiram N., vaginal operations for retroversions and retroflexions of the uterus, with a critical review of fifty-seven cases of vaginal suturing of the round ligaments (the author's operation), 376.

Virchow, attitude of, toward evolution, 939; the accident and illness of, 839; views of, on the parasitic theory of diease, 580.

Viscera, suture of solid, 386.

Vision, physiology of, 988.

Vivisection, benefits of, 144, 982.

Volition and sensation, 567.

Volta Bureau, report on deaf-mute schools by the, 58.

Volvulus cæci, 440 cœliotomy twice in the same patient for, 344; of the small intestine, 199.

Vomiting, recurrent, 304; recurrent, in children, 911; stercoraceous, of hysterical origin, 831.

W

Walker, William A., case of rattlesnake bite, 151.

Wallace, Raymond, biogenesis and heredity, 763.

Water, administration of, in disease, 266; food value of, 771; pathogenic microbes in potable, 591; supply, proposed filtration plant for the New York, 942; thermoregulating function of, 639.

Weaklings, overproduction of, 939.

Weather, effect of, on health, 280; effect of, on the death rate, 460.

Weil's disease, Widal reaction in, 187, 346.

Weir, Robert F., a new use for the useless appendix in the surgical treatment of obstinate colitis, 201.

Wells, Brooks H., repeated ectopic gestation, 801.

Wells, J. Hunter, the medical missionary's work in Korea, 826.

Wesley M. Carpenter lecture, 631.

West Africa, sanitary work in, 313.

West Indies, medical aspects of the, 17.

White slave trade, congress for the repression of, 382.

Whooping-cough, prophylaxis of, 671; specific serum for, 703; trephining in the cerebral hemorrhage of, 799.

Wiggins, J. L., traumatic injuries of the liver, 535.

William Pierson Library Association of Orange, 856.

Wolff's law of transformation, 235.

Wolf, Henry J., malaria as a complicating factor in the diagnosis of appendicitis, 54.
Women, cancer in, 274.
Wood's Hole, a summer in, 303.
Workshops, medical inspection of, 786.
Worrall, H. R. L., the medical treatment of hernia in Arabia, 896.
Wounds, treatment of, 80.
Wright, Frederick A., mosquitos and malaria, 63.
Wrist-drop, appliance for, 232.
Wry-neck, spasmodic, 236; spasmodic, in exophthalmic goiter, 119.
Wynkoop, D. W., infectious bronchopneumonia, 654.

Y

Yale University, new building for scientific purposes at, 40.
Yaws, 189.
Yeast, therapeutic uses of, 626.
Yellow fever, 313; affiliations of, 548; alleged parasite of, 937; diagnosis of, from malignant malaria, 548; discussion on, 993; diseases allied to, 740; eradication of, from Havana, 648; infection of vessels with, 894; mosquitos in relation to, 196, 200; mosquitos on board vessels in quarantined ports as factors in the transmission of, 256; mosquito theory of, in Brazil, 585; not carried by fomites, 795; on ship-board, 198; on the U. S. S. *Plymouth* in 1878 and 1879, 530; quarantine against in Havana, 791; repression of, 343; treatment of, 143, 546.
Young, J. V., hunchback; rectifying of spinal deformity by forcible traction; immediate straightening, 173.

Z

Zola, Emile, a study of, 659.
Zoster, malarial origin of, 224.
